12. To replace the bearings, first support the crankcase half with a block of hard wood beneath the bearing hole. Heat the case around the bearing hole as on removal. Use a bearing driver or a block of hard wood large enough to cover the entire bearing and drive it straight home until seated.

13. Press in new oil seals using a block of wood large enough to cover the entire seal. Note that the cupped side of the seal should face the bearing, while the other side should be flush with the crankcase surface. The seals should be aligned straight in their seats.

The right crankshaft oil seal is placed on the inside of the bearing, while the left oil seal is on the outside of its bearing. Grease the lips of the oil seals before inserting any shafts into them.

The lips of the seals must bear properly

against the shafts inserted into them. Sometimes they become turned out when the shaft is inserted. If so, move the shaft back and forth until the lips are correct.

CRANKSHAFT ASSEMBLY

1. Make a visual inspection of the crankshaft. Note the condition of the bearing surfaces, wear on the taper, and worn or broken primary gear splines.

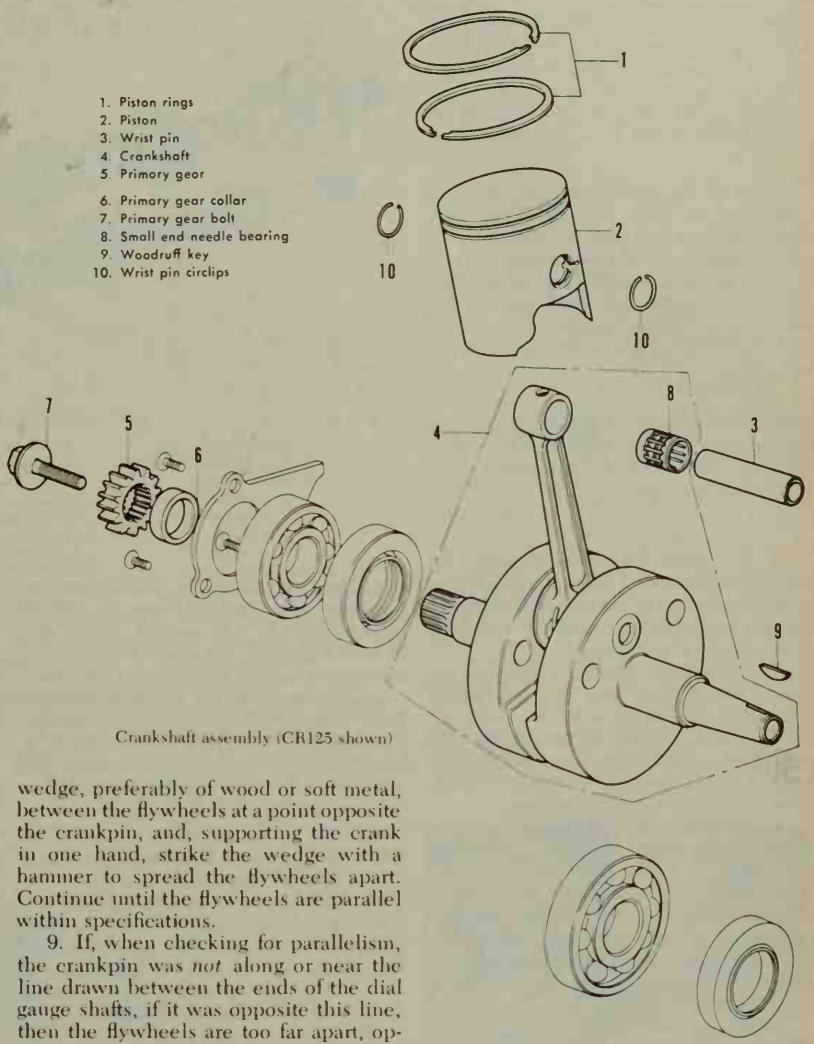
2. Check the connecting rod for any visible damage, especially discoloration at the lower end. Check the small end of the connecting rod for scoring of the bore.

3. Check the connecting rod for vertical (up-and-down) movement on the crankpin, as well as for excessive lateral movement which would indicate a worn big end bearing.

Rotate the rod around the crankpin noticing any binding or rough movement. If any of the above conditions are found, the crankshaft assembly will have to be replaced as a unit, as the crankshaft cannot be disassembled for service to the big end bearing or connecting rod.

4. Crankshaft run-out is usually checked with a pair of V-blocks, or a jig and two dial gauges. Mount the crankshaft with the V-blocks as close to the flywheels as possible, and the dial gauges at the end of the shafts. Crankshaft alignment should only be undertaken by a competent, experienced mechanic.

NOTE: *For crank alignment, a brass hammer is used. Do not use a steel one.*



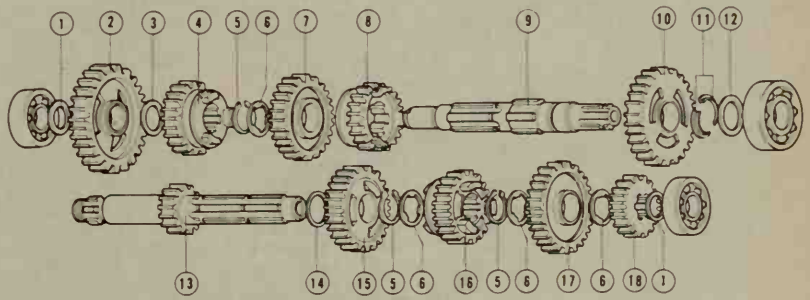
5. The crankshaft must be checked for eccentricity and for parallel flywheels. The crankshaft flywheels are eccentric if one has been rotated slightly ahead of the other. The flywheels are nonparallel if they lean towards or away from each other.

6. Turn the crank in the jig. If the dial gauges do not move the same distance, and do not begin and end their movement at the same time, the crankshaft flywheels are both eccentric and nonparallel. In this event, eccentricity must be taken care of first.

7. To correct eccentricity, rotate the crank until the drive-side dial gauge indicates the high point of its travel. Stop at this point. Imagine a line drawn from one of the dial gauge shafts to the other. Mark the spot on the drive-side flywheel at the spot this line would cross it. Remove the crankshaft from the aligning jig, and, with the brass hammer, strike this spot on the drive-side flywheel smartly. Be sure you are holding the crank assembly by the magneto-side shaft while doing this. Recheck alignment, and repeat this procedure as long as necessary until the dial gauge needles begin and end their travel at the same time.

8. Replace the crankshaft assembly in the jig, and rotate it until the needles reach their highest point of travel. If the crankpin lies along an imaginary line drawn between the ends of the two dial gauge shafts, the flywheels are evidently pinched together opposite the crankpin.

To correct this condition, insert a wedge, preferably of wood or soft metal, between the flywheels at a point opposite the crankpin, and, supporting the crank in one hand, strike the wedge with a hammer to spread the flywheels apart. Continue until the flywheels are parallel within specifications.



Crankshaft assembly (CR125 shown)

9. If, when checking for parallelism, the crankpin was *not* along or near the line drawn between the ends of the dial gauge shafts, if it was opposite this line, then the flywheels are too far apart, opposite the crankpin. In this case, once again make a mark on either flywheel where the imaginary line would cross it. (Note that the crank should be positioned so that the dial gauges are at the highest point of their travel). Remove the crank, and, with the brass hammer, strike the flywheel sharply on the *side* to bring the flywheels closer together. Check again, and repeat the procedure until crank run-out is within specification.

10. Clean the crank assembly thoroughly, and oil the big end bearing well.

TRANSMISSION

Unless the transmission has been malfunctioning in some way it is not recommended that it be disassembled for inspection. If the transmission has a malfunction this should indicate what to look for. If the transmission grinds when

shifting or shifting is difficult, the shift forks, shift drum, and shift fork shafts should be suspected. If the transmission jumps out of gear, the mainshaft, countershaft, and the shifting forks should be inspected for wear, or a bent condition.

1. With the gear clusters in the right crankcase measure the gear backlash. Lock one gear into position and move the other against it while measuring total rotational movement with a dial gauge. This movement is the gear backlash for that set of gears. If the backlash exceeds 0.2 mm (0.008 in.), replace both gears in the set.

NOTE: *Whenever replacing transmission gears they should be replaced in pairs, that is, both mainshaft and countershaft gears.*

2. The gears should be checked for worn, chipped, or broken teeth. If any gear is badly worn, the gear with which it meshes should also be replaced, even if it does not show any damage.

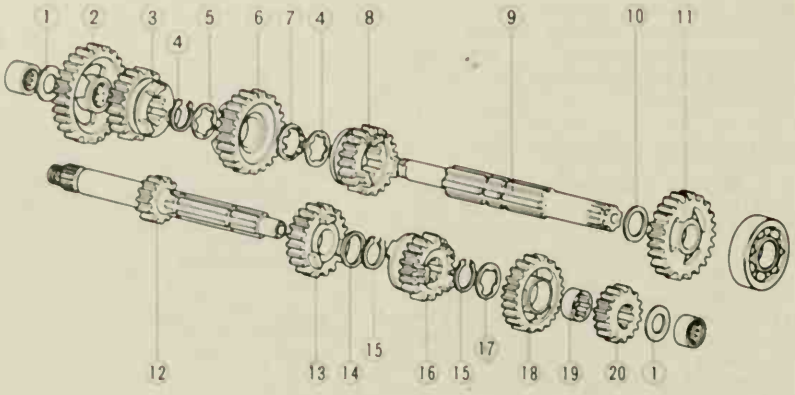
3. Inspect the engaging dogs on the gears, and replace any gear on which they appear chipped or worn.

4. Check the splines on the gears so equipped, and the corrresponding splines on the mainshaft or countershaft. They must be in good condition.

5. Check the gearshift forks for a bent or worn condition. Replace if they are damaged.

6. Measure the outside diameter of shift fork shaft; if it is less than 9.92 mm (0.3906 in.) for 125 and 175 cc models or less than 11.92 mm (0.4693 in.) for 250 cc models, replace it. Check the shaft for a bent condition. Replace it if bent.

7. Measure the inside diameter of the gearshift forks; for 125 and 175 cc models, replace any that have an ID greater than 10.05 mm (0.3957 in.). The ID of the left and right gearshift forks on 250 cc models should not exceed 12.05 mm (0.4744 in.) while the center shift fork ID should not exceed 34.08 mm (1.3417 in.).



8. Measure the thickness of the shift fork fingers; 125 and 175 cc models should be replaced if they are found to be less than 4.5 mm (0.1772 in.), while the minimum thickness for 250 cc models is 4.6 mm (0.1811 in.).

9. 250 cc models only: measure the OD of the gearshift fork drum, replace it if less than 33.9 mm (1.3346 in.).

10. Inspect the pins which locate the shift forks to the gearshift drum. They should be replaced if they are chipped or show signs of wear.

11. Check the gearshift return spring for a weak or broken condition.

12. 125 cc models only: check the kick-starter return spring for a weak or broken condition. Replace if condition is doubtful.

Lubrication System

MT models have an automatic oil injection system to lubricate the crank assembly (piston, con rod bearings, left-side crankshaft bearing). The CR models use oil mixed with the gasoline to lubricate these components.

All models have the transmission, clutch, and right-side crank bearing lubricated by an oil bath.

CR and MR Models

OPERATIONAL DESCRIPTION

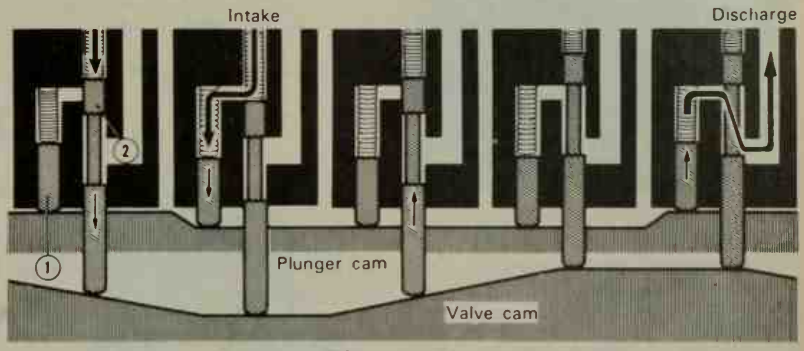
The connecting rod bearings, cylinder, and left-side crankshaft bearing are lubricated by a gas-oil mixture. This mixture is a premix to the ratio of 20 parts gas to 1 part oil. Refer to the "Gas-to-Oil Ratio" chart.

SERVICE

1. Using a high grade motor oil (SAE 40), or two-stroke oil, prepare a premix in the ratio of 20 to 1. Be sure to use a clean container and mix thoroughly before filling the fuel tank.
2. Use gasoline with a pump octane rating of 91 or higher.
3. It is recommended that you use a mineral base oil as vegetable oil is more likely to separate from the gasoline.

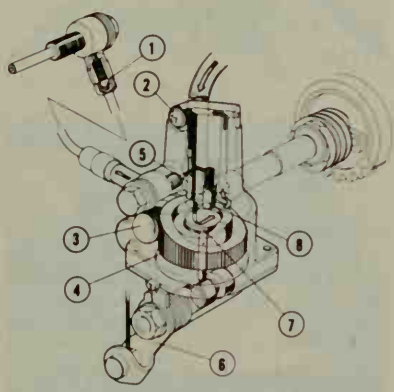
CAUTION: *Do not mix oils made from different bases.*

4. Use the premix within 24 hours after mixing. Once mixed, the oil loses its lubricating properties with time.
5. Use oil within one month after opening the can as oil left in an open container may oxidize.



MT Models

OPERATIONAL DESCRIPTION



The oil pump is a two plunger unit. One plunger is for pumping the oil; the other (the plunger valve) opens and closes the intake and discharge passages in the pump. The upper surface of the cam gear has two concentric circle cams formed on it. The plunger rides on the inner cam while the plunger valve rides on the outer cam surface. The plunger and the plunger valve are held against the cam by springs. As the cam rotates the plunger valve is lowered exposing the intake and blocking the discharge passage. At this point the plunger is lowered drawing in fresh oil from the oil tank. Then the plunger valve is raised exposing the discharge passage and closing off the intake. At this point the plunger is raised, forcing the fresh oil to the engine.

A check valve is incorporated into the banjo fitting at the engine side of the oil feed line to prevent crankcase pressure from returning oil to the pump.

The amount of oil pumped to the engine is controlled by the oil control cable which is connected to the throttle cable. As the throttle is opened, the control lever on the oil pump is raised, rotating a cam under the control rod in the pump. With the throttle closed, the control rod is in the "up" position holding the plunger from riding on the cam in the lowest position; thus, the plunger does not take a full stroke, decreasing the amount of oil pumped. As the throttle is opened, the control rod is lowered below the cam surface allowing the plunger to ride on the cam during the full cycle. In this position the plunger takes a full stroke and the amount of oil pumped to the engine increases. Thus the engine receives a supply of oil determined by its needs.

SERVICE

Under normal conditions, lubrication system service is confined to adjusting the oil pump cable and cleaning the oil tank filter.

If the oil tank, pump, or lines are removed or disconnected for any reason (such as engine removal), the lines should be bled of possible air bubbles.

CAUTION: *Due to the exacting tolerances to which it is made, the oil pump should never be disassembled. If any lubrication system failure is traced to the pump, the unit must be replaced rather than repaired.*

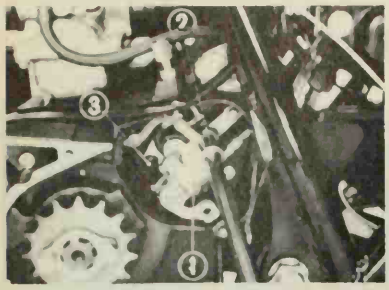
OIL PUMP

Location

The oil pump is located at the rear of the left engine crankcase. The pump is driven off the crankshaft by way of the tachometer driveshaft, which is driven from the right-side of the engine.

Bleeding

1. Before attempting any bleeding operation, ensure that the oil tank has a sufficient quantity of oil.
2. Remove the drive chain, left crankcase cover, and the oil pump cover, which is secured by two screws.
3. Remove the oil bleed screw.



Oil pump bleed screw (1)

4. When the oil comes out continuously with no sign of air bubbles, install the bleed screw and check for leakage.
5. Install the oil pump cover, drive chain, and the left crankcase cover.
6. Start the engine. Using half throttle or less run the engine for seven minutes checking for air in the oil lines. If air bubbles are present, repeat the bleeding operation. If no air is present, the oil pump is bled completely.

Removal

1. Remove the drive chain, left crankcase cover, and the oil pump cover.
2. Remove the plastic sidecover over the oil tank and disconnect the oil line from the oil tank. Plug the oil tank to prevent leakage.
3. Raise the oil pump control lever, remove the control cable pin and disconnect the cable.
4. Remove the banjo bolt from the oil pump and disconnect the oil feed line from the pump.

Removing the oil pump banjo bolt (2) and oil pump securing screws (3)

5. Remove the two mounting screws and pull the pump off.

Installation

1. Slip the oil pump feed line over the fitting on the oil pump and secure with a spring clip.
2. Pass the oil line through the inlet grommet hole and pull it toward the oil tank.
3. Fit the pump drive into the opening in the crankcase. Be sure to line up the slot on the driveshaft with the tab on the oil pump. Push the pump on by hand until it is perfectly mated with the crankcase, and secure it with the two mounting screws.
4. Connect the engine oil feed line to the pump with the banjo bolt.
5. Connect the oil line to the oil tank and secure it with a spring clip.
6. Connect the oil pump control cable. Bleed the oil pump as described above. Adjust the oil pump cable so that the lines on the pump and on the control lever are aligned when the throttle is closed.

OIL FILTER SCREEN

A filter is incorporated into the feed pipe at the bottom of the oil tank.

Oil line joint (nut (MT125)

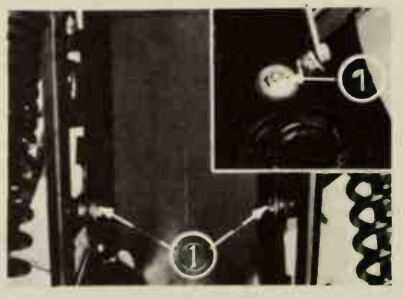
1. Drain the oil tank.
2. MT125: unscrew the joint nut, pull the oil pipe free of the tank, and remove the filter screen.

3. MT250: having disconnected the oil feed line from the plastic fitting, unscrew the fitting and remove it and the filter from the oil tank.

4. Clean the filter screen thoroughly in a solvent and dry it completely. Inspect it for rips or punctures, and replace it if damaged in any way.

5. Check the condition of the rubber O-ring on the fitting, and replace it if it is cracked or damaged.

Oil tank filter (MT250)



6. Install the screen, tighten the joint nut (125) or the plastic fitting (250). If you have a 250, make sure that the plastic fitting is no more than hand-tight. Refill the oil tank, and bleed the oil pump as described above.

Carburetor

REMOVAL AND DISASSEMBLY

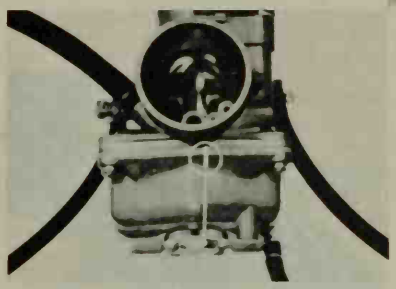
Each of the machines covered in this section uses a Keihin carburetor. Although there are a few differences in carburetor construction for each model, the disassembly procedure is essentially the same for all of them. Refer to the carburetor illustrated for your machine.

1. Turn the fuel petcock to the OFF position. Drain the float bowl by removing the drain plug and catching the gas in a suitable container. Disconnect the fuel line from the carburetor.

NOTE: *If you are just trying to remove the main jet, this can be done through the drain plug opening without removing the float bowl.*

2. MT250 only: Remove the oil feed line from the intake manifold.

CAUTION: *Cover the open end of the oil line with a plastic bag secured with a rubber band.*



3. Remove the two bolts which secure the intake manifold to the cylinder. Loosen the band holding the carburetor to the air cleaner and separate the carburetor and manifold from the machine. To remove the manifold from the carburetor, loosen the clamp. On the MT and MR models, note that the carb must be pulled *straight* off the manifold due to its positioning tab.

4. Unscrew the top of the carburetor and remove the throttle slide assembly.

NOTE: *If the throttle slide does not need servicing, place it out of the way in a plastic bag secured with a rubber band around the throttle cable.*

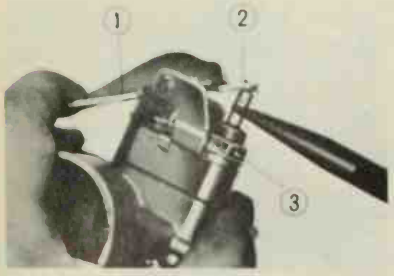
5. If necessary, the throttle slide assembly may be removed from the throttle cable by compressing the spring against the carburetor top, removing the needle plate retaining spring clip and pulling the plate up against the return spring. Pull the throttle cable out of the slot in the slide and remove the throttle slide, needle plate, return spring and the carburetor top from the cable.

6. Push the needle and its clip out of the top of the throttle slide. (Before removing the needle clip note its position on the needle).

7. Remove the overflow and breather hoses from the carburetor body.



8. Remove the starter plunger by bending the lockwasher tabs back and removing the locknut. Pull the starter plunger out of the carburetor.

9. Turn the carburetor upside down. Remove the four phillips head screws which secure the float bowl. Then tap the float bowl very lightly to break the seal. Remove the float bowl.

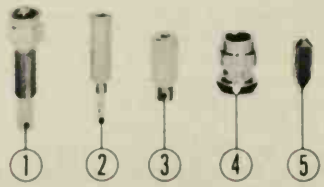
10. Push out the float pivot pin, and very carefully remove the float and float needle.

11. Remove the phillips head screw located directly behind the float needle seat. Remove the float needle seat set plate and pull out the seat.



12. Unscrew and remove the main jet. Remove the jet holder. Unscrew the needle jet on all except the CR250. On this model, the needle jet is a light press fit in the carburetor body, and is removed by pressing it out from the bottom with a wooden dowel or the like. This jet is best left in place. It is important to note that if removed, the needle jet must be installed with the cutaway at the top facing the *engine side* of the carburetor.

Removing the float pivot pin, needle retaining plate (3), and float needle (4)

13. Remove the two phillips screws securing the float bowl baffle plate and take out the plate.

NOTE: *Be very careful when removing the jets as they are soft brass which can be damaged very easily.*

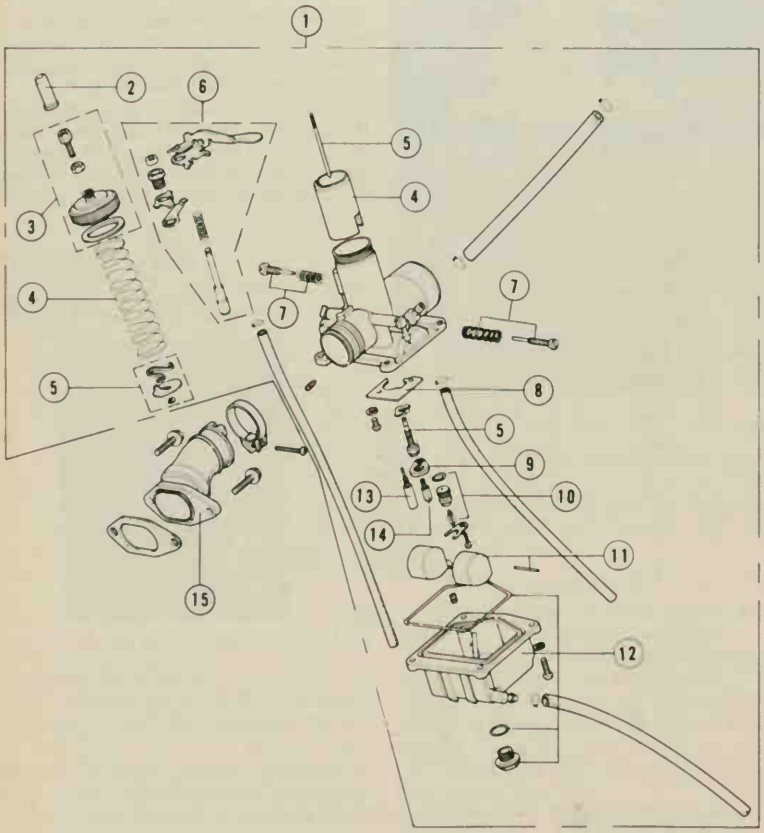
14. Remove the pilot air screw and spring, and the idle adjusting screw.



ASSEMBLY AND INSTALLATION

1. Assemble the starter plunger components and install the plunger in the carburetor. Be sure to bend back the locking tabs on the lockwasher.

2. Install the float needle seat and set should be replaced. If the components are more than two years old, new ones should be fitted before attempting to tune the carburetor, or taking remedial action to correct a rich condition (such as lowering the needle position).

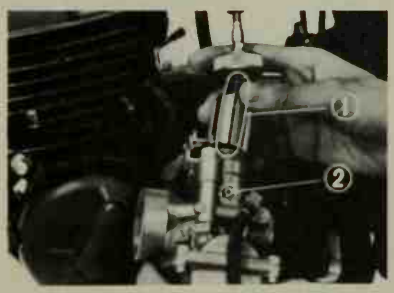
3. Install the baffle plate, needle jet, pilot jet, jet holder and main jet.



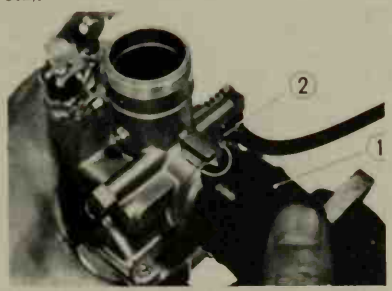
CAUTION: *Do not over tighten the jets.*

4. Place the needle in its seat, then position the float over the needle and slip in the float pivot pin. Install the float bowl O-ring in the float bowl making sure that it is properly seated. Install the float

bowl and tighten the four phillips head screws in an "X" pattern until secure.

5. Install the pilot air screw and spring. Screw in the pilot air screw until it is lightly seated, then back it off 1¼ turns (MT and MR models) or 1½ turns (CR models). This is an approximate setting, and may have to be readjusted when the engine is started.

6. Install the clip on the needle in the same groove from which it was removed. Install the needle in the throttle slide.



Installing the throttle slide; the notch on the inside of the carburetor bore (2) must engage the slot in the throttle slide (1)

7. Slip the rubber cover up over the throttle cable sleeve, then place the carb cap, washer, return spring and needle plate over the cable end. Insert the cable end pin in the slot in the slide and lower the needle plate into the slide and secure with a spring clip. Place the return spring in the slide. Install the slide in the carburetor with the cutaway portion facing the air cleaner. Screw the cap onto the carburetor body.

8. Install the idle adjusting screw, screw it in until it just contacts the slide.

9. Install the carburetor on the intake manifold pushing it straight on. Take care to line up the tab on the carb with the slot in the intake manifold (MT and MR models).

When installing the carburetor, be sure that the tab and slot are properly engaged

10. Install the carburetor and intake manifold on the machine making sure that the manifold gasket or O-ring is in place. Connect the air cleaner and tighten the air cleaner clamp.

11. MT250 only: install the oil feed line to the intake manifold. Be sure to use a washer on either side of the banjo fitting.

NOTE: *Check that the throttle slide moves freely in the carburetor from wide open to fully closed before starting the engine.*

12. Start the engine. Check for air leaks at the manifold. Adjust the pilot air screw and idle adjusting screw.

Fuel Petcock and Lines

Cleaning

1. Turn the petcock to off.
2. Unscrew the sediment bowl, remove the O-ring and filter screen.
3. Clean all the parts in solvent. Check that there are no holes in the filter screen and that the O-ring is not nicked or out of shape.
4. Run a little gas through the petcock to flush out any dirt (catch the gas in a suitable container). Use both the ON and RES positions to check for operation.
5. Replace the filter screen, O-ring, and the sediment bowl.

Disassembly

1. Drain and remove the fuel tank.
2. Remove the sediment bowl, O-ring and filter screen.

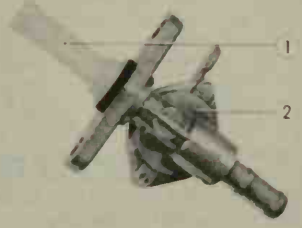
If a plastic fuel line is fitted as a replacement, check for brittle condition or discoloration. These are signs of age, and if present, the fuel line should be replaced.



Assembly

1. Install the fuel valve gasket, fuel lever, spring, and fuel lever setting plate. Secure with the two screws.
2. Be sure that the petcock O-ring is properly seated and install the petcock on the fuel tank, securing it with the two mounting screws.

Electrical Systems

Ignition Circuit

MT AND MR MODELS

Hard starting or misfiring are often caused by ignition system troubles, but since electrical malfunctions are often trickier to pin down than carburetor faults, it is wise to ensure that systems other than the ignition are in serviceable condition before beginning any work.

1. In the event of hard starting, misfiring, or cutting out, first check that the spark plug is not worn or the insulation cracked, that it is the proper heat range, and that all electrical connections are clean, dry and tight. Check the ignition timing and be sure it is correct.

2. Remove the spark plug, clean it thoroughly, or replace it with a new one; gap the plug to 0.6–0.7 mm (0.024–0.028 in.). Connect it to its cap, and ground it against the cylinder head. Kick the engine over briskly. The spark produced should be thick and blue.

3. If there is no spark, or if the spark is weak and yellow, check the condition of the contact breaker points. Inspect, clean, and gap the points or replace them if they are badly pitted or worn. If excessive arcing or sparking at the points is noted while the machine is running, the problem may be the condenser. A defective condenser will also cause new points to wear out quickly.

4. If the problem is not in the points or the spark plug, the spark plug cap should be checked. Noise suppressor caps are fitted, which are designed to eliminate radio interference and provide a hotter spark by means of a resistor in the cap. Sometimes the resistor breaks down, and the cap then becomes an open circuit. Remove the cap from the spark plug lead, and ground the end of the lead against the cylinder head. If a fat, blue spark is produced when the engine is kicked over, the problem was the cap. Replace it with a new one.

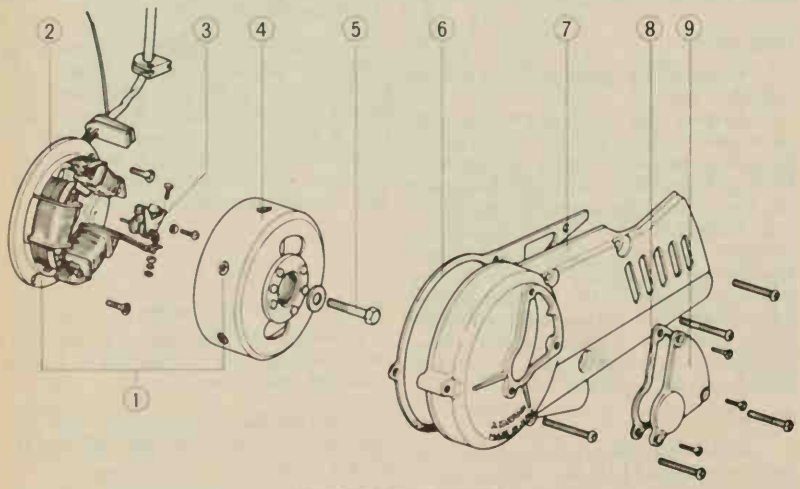
5. If the cap checks out okay, carefully inspect the cable itself. Check for dirt or grease, cuts or cracks in the insulation, moisture, etc. If the lead is damaged, it must be replaced. This also involves replacing the coil.

6. If the trouble has not been pinpointed, the ignition coil should be checked. An ohmmeter should be used.

a. Disconnect the black/white coil wire and check for continuity between the black/white wire and ground at the coil mounting bracket. This is a test of the coil's primary winding. Resistance should be only a few ohms at most. If it is very high or infinite, the primary winding is broken, and the coil must be replaced.

b. Leaving the black/white wire disconnected, check for continuity of the secondary winding by attaching one of the ohmmeter leads to the spark plug lead and the other to ground at the coil mounting bracket. Continuity should exist and the resistance should be several thousand ohms. If the resistance is infinite, the secondary winding is broken and the coil must be replaced. If the resistance is significantly lower than this amount, the secondary winding insulation is breaking down and replacement of the coil is necessary.

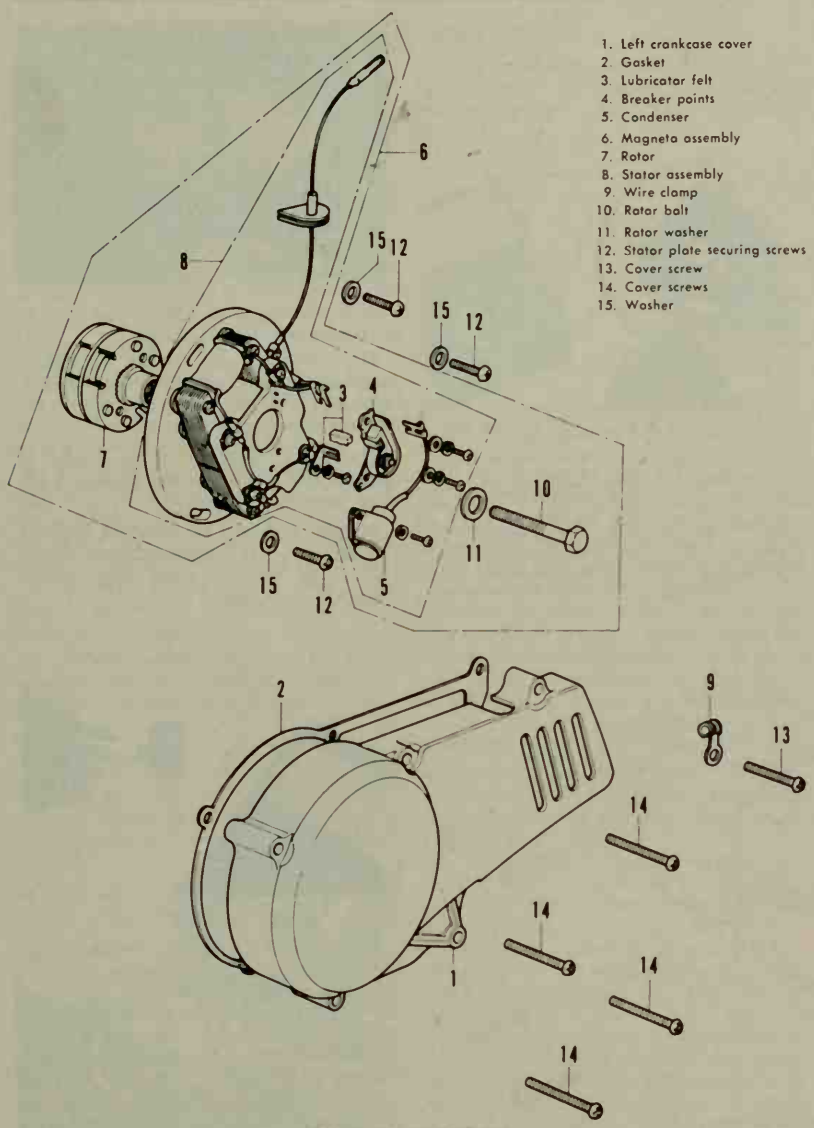
7. Even if continuity is present in the coil windings, it is possible that the coil is still defective. Replacing the coil temporarily with one which is known to be serviceable is recommended.



8. The condenser can be checked if a capactance tester is available. Condensers should have 0.25 mf capacitance. Checking with a megger should yield a resistance of 10M ohms at 1000v.

As noted above, sparking at the points or points which pit or burn rapidly would indicate a defective condenser. Bad condensers will cause mounds and matching depressions on the points. Refer to the illustration.

NOTE: *If the trouble has not yet been found, and the problem is a no-spark (rather than a weak spark) condition, it is advisable to check the operation of the ignition switch and kill switch. A defective switch may be grounding the magneto.*



9. If the switches are in working condition, the magneto itself must be checked. Remove the left sidecover and the magneto flywheel as outlined in the "Engine and Transmission" section. The special puller bolt must be used to remove the flywheel.

10. Make a close visual inspection of the breaker points. Check for loose, frayed, or broken wires. Check the inside of the flywheel for any scoring or wear which would indicate that the flywheel is contacting the core ends. This condition

must be remedied upon installation. If this has occurred, check for any play in the crankshaft which would indicate a bad crankshaft bearing. Other reasons may be improper mounting of the coil cores or flywheel, worn crankshaft taper, or flywheel hub taper surface. If the hub taper is damaged, the flywheel should be replaced. Also inspect the flywheel for any cracks or fractures. If present, replace the flywheel.

11. Check for continuity of the primary exciting coil after disconnecting the wire running to the ignition coil and placing a piece of business card or the like between the breaker points. Connect the continuity tester or ohmmeter to the black/white wire on MT models or the black/yellow wire on MR models and the exciting coil ground wire. If no continuity exists, the coil is broken and must be replaced.

12. Check to ensure that the exciting coil core is properly grounded to the stator plate. Use an ohmmeter or continuity tester. If no continuity exists between the core and the plate or if resistance is high, remove the core from the backing plate and sandpaper the contact surfaces. Clean both after sanding, then install.

The mounds on the breaker points indicate a bad condenser

CR250

In spite of the differences in construction already noted, the CR250 ignition circuit is essentially the same as that found on the MT models. Note that the condenser is mounted on the magneto stator plate rather than with the ignition coil.

Continuity tests should be carried out in the event of ignition problems as described in the previous section. Note the following differences:

1. Plug gap is 0.5–0.6 mm (0.020–0.024 in.).

2. The ignition coil wire is red rather than black/white as for the MTs. Take primary coil continuity readings between the red coil wire and ground.

3. The magneto rotor is removed with a special puller. Refer to the "Engine and Transmission" section.

CR125

This model is fitted with a CDI system. Continuity tests for the ignition coil can be carried out with an ohmmeter in the same way as described for the MTs. The CDI unit itself, however, is not testable and if other possible trouble spots have been eliminated, the unit should be replaced.

1. In the event of ignition problems, first check for loose or wet wiring connections, then for spark plug, cap, and lead problems.

2. Check the continuity of the ignition coil windings.

3. Check the kill switch.

4. Check the continuity of the pulser and the exciter coils located on the magneto stator plate.

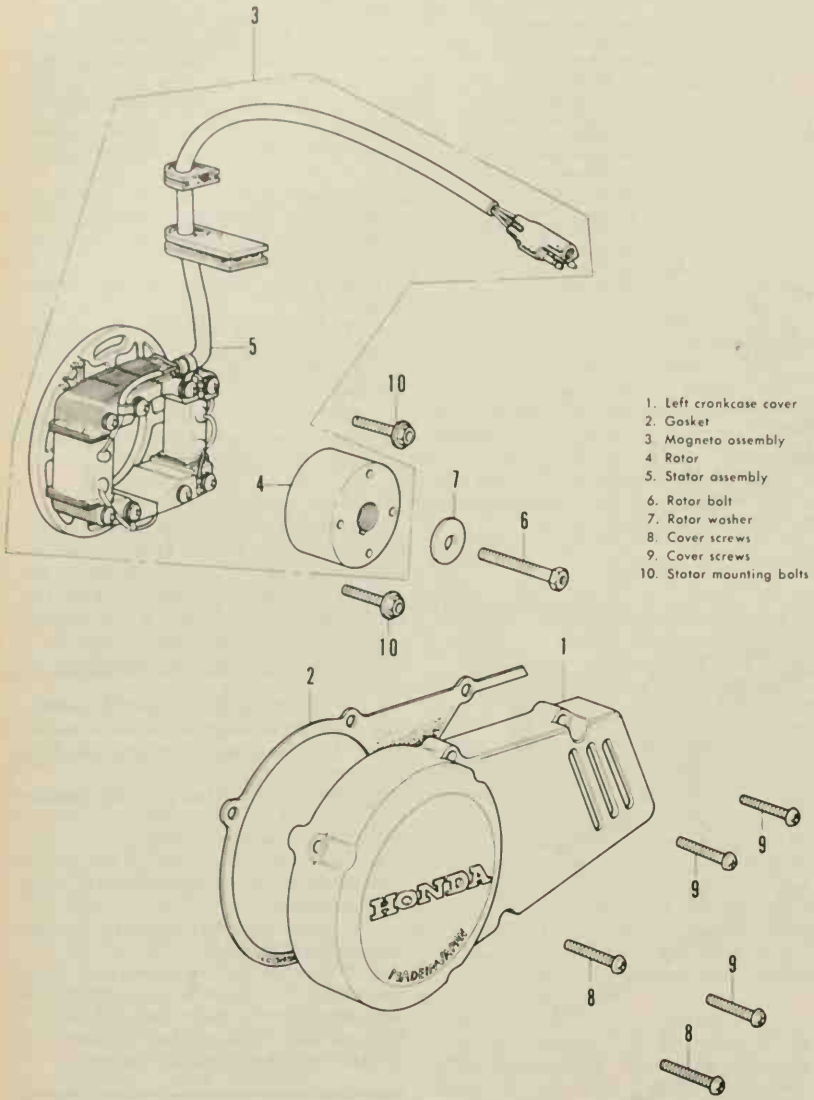
5. If the trouble has not been located, replace the CDI unit.

6. When the left sidecover has been removed, check that the magneto rotor is not contacting the stator base. Clearance between the two should be 0.5 mm (0.020 in.) all the way around the rotor.

Charging System

The following applies only to MT and MR models. An ammeter and voltmeter should be on hand for the following tests. An ohmmeter or continuity light should also be available for testing the rectifier.

NOTE: *Before attempting any charging system test, be sure that the battery has a full charge and does not have any weak or shorted cells.*

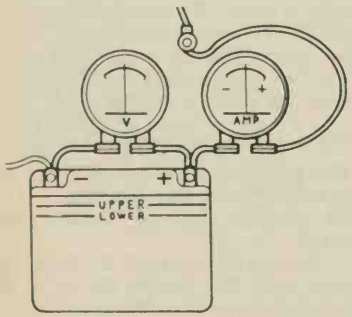


ALTERNATOR OUTPUT

The following tests should be carried out in the event that the battery goes dead often or will not become fully charged.

1. Use a trickle charger to charge the battery until the specific gravity of the electrolyte is 1.260–1.280 at room temperature.

2. If the battery will not take a full charge or if one or more cells are lower than the others, the trouble is in the battery and it should be replaced.



3. Disconnect the red (positive) lead from the battery and connect it to the pos-

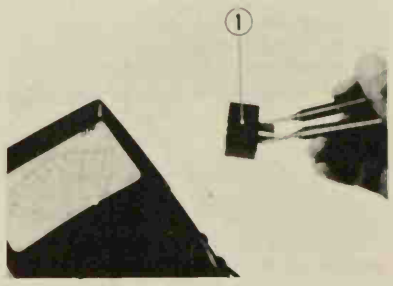
itive side of the ammeter. Connect the other ammeter lead to the battery positive terminal. Connect the voltmeter across the battery terminals.

Hook-up for checking alternator (lighting coil) output

4. Start the engine and record the voltmeter and ammeter readings at the various rpm with the headlight and taillight *on* and *off*.

5. Readings should be within 10% of the standard values shown in the charts. Differences in temperature will cause slight variatons in alternator output. If readings are significantly lower than the standard values, check the rectifier and the alternator.



RECTIFIER

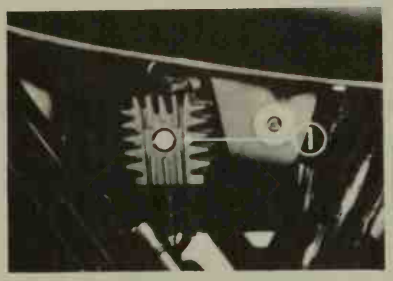
The purpose of the rectifier on MT125 and 250 is to change the alternating current produced by the lighting coils to direct current to charge the battery. The MT125 uses a simple half-wave rectifier consisting of a single diode. The diode will pass current in one direction only. It therefore can change alternating current into pulsating direct current.

The rectifier used on the MT250 is more complicated, utilizing four diodes. Its purpose is the same, however. This is a full-wave rectifier.

The MR175 rectifier has two diodes. It changes AC to DC for the ignition coil, since there is no battery.

Rectifiers should be checked with an ohmmeter. Set the scale knob on the K-ohm range. Do not use a high-voltage ohmmeter (megger).

Checking the rectifier (MT125)



The rectifier should be checked if the battery will not hold a charge, if it becomes discharged, if the horn and stoplight-taillight will not work with the battery disconnected and the engine running, or if the headlight seems too bright.

On MT models, the rectifier should be checked if the battery will not hold a charge, if it becomes discharged, if the horn and stoplight-taillight will not work with the battery disconnected and the engine running, or if the headlight seems too bright.

CAUTION: *If the MT250 rectifier is removed from the machine, exercise care that the mounting screw is not overtightened when it is installed.*

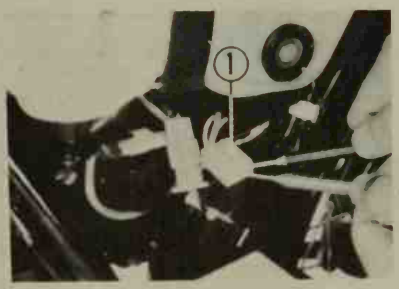
MT250 rectifier location

MT125, MR175

1. Disconnect the rectifier red and yellow leads on MT models, or the black/yellow green and black/white leads on MR models, at the rectifier.

2. Connect the positive lead of the ohmmeter to either one of the leads, and the negative lead to the other.

3. Note the resistance reading. It should either be a few ohms or very high.



4. Reverse the ohmmeter leads, and note the resistance. It should be opposite of the first reading.

5. If the ohmmeter indicated the same resistance in both cases, the rectifier is defective and must re replaced.

MT250

This rectifier has four leads, and each set must be tested in the same manner outlined for the MT125, above.

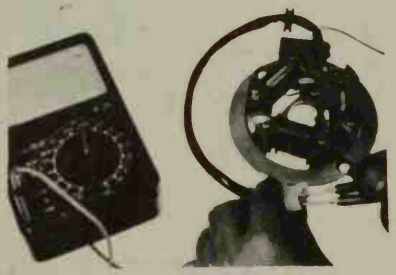
1. Disconnect the rectifier leads at the coupler.

Checking the MT250 rectifier at the plastic coupler

2. Connect either ohmmeter lead to the red/white rectifier lead and the other ohmmeter lead to the pink rectifier wire.

3. Note the resistance. It will either be. very high (no continuity) or a few ohms (continuity).

4. Reverse the ohmmeter leads. Note the resistance. It should be the opposite of the first reading.



5. If the ohmmeter reads the same resistance in both cases, the rectifier is defective and must be replaced.

6. Repeat this procedure with the ohmmeter connected to the following pairs of leads:
Pink and green
Green and yellow
Yellow and red/white

7. If any of these pairs of leads shows continuity in both directions or complete lack of continuity, the rectifier must be replaced.

ALTERNATOR

1. The alternator lighting coils should be checked in the event that the battery and rectifier are found to be operating correctly.

Checking the alternator for short or open circuits

2. The MT125 has two lighting coils mounted to the magneto stator. Use an ohmmeter or continuity light to check for continuity. Disconnect the magneto wires at the plastic coupler. Remove the magneto flywheel. Check for continuity between the white/yellow wire and the stator. If there is no continuity, either the lighting coil is broken internally or has a poor ground connection at the stator. Now check for continuity between the yellow wire and the stator. If there is none, the other coil is either broken or has a bad ground at the stator. To eliminate needless work, check the continuity of the lead wires themselves before replacing the coils.

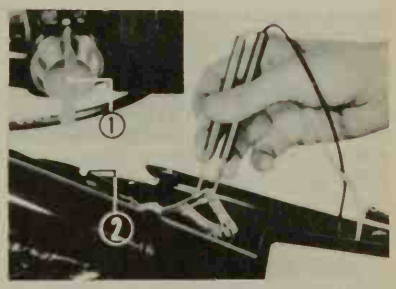
3. The MT250 is also fitted with two lighting coils on the stator, but the internal wiring is somewhat different than the MT125. Remove the magneto flywheel; disconnect the magneto wires at the plastic coupler. With an ohmmeter or continuity light, check for continuity between the white/yellow lead and the stator. If there is none, the coil is either broken internally, or has a bad ground to the stator.

Check for continuity between the pink and the yellow leads. If there is none, one of the coils may be broken internally.

Before replacing either of the coils, check that the leads themselves have continuity.

4. On the MR175, check for continuity between the yellow lead and ground, as in step 2, above.

Switches



The operation of the electrical switches can be checked with a continuity light or an ohmmeter.

Switches should be checked when the components they control fail to operate.

In addition, main switches (MT models) and ignition "kill" switches (all models) should be checked in the event of a no-spark condition.

IGNITION SWITCH

The ignition switch (or "kill" switch) is located near the throttle twist-grip. When the switch is in the "run" position, it constitutes an open circuit—no current passes through. When "off," the switch is grounding the low tension lead of the ignition coil.

Checking the ignition "kill" switch

The kill switch leads are connected beneath the gas tank. They are black/white and green on all except the CR250, where they are black and green.

Disconnect the two leads and connect the continuity tester or ohmmeter across them. When the switch is in the "run" position, there should be no continuity (infinite resistance; continuity light off). When the switch is turned to either "off" position, the testing device should show continuity.

If there is continuity when the switch is in the "run" position, the kill switch is grounding out the ignition circuit which is probably why the machine will not start.

MAIN SWITCH

MT models are fitted with a main (key) switch below the gas tank. When the switch is "off," the low tension side of the ignition circuit (black/white wire) is grounded to the frame through the green wire.

When the switch is "on," the red battery (positive) lead is connected through the black wire to power the horn, turn signals, and taillight.

To test the switch, disconnect the connector near the switch. Use an ohmmeter or continuity light to check for continuity between the black/white wire and the green wire. When the key is off, continuity should exist. When the key is on, there should be no continuity. If continuity exists when the key is in the "on" position, the ignition circuit is being grounded and the machine will not start.

When the key is on, check for continuity between the black and the red wires. Continuity should exist. If it does not, the battery is being prevented from working the horn and lights by a defective switch.

The main switch must be replaced if defective.

BRAKE LIGHT SWITCHES

Disconnect the black and green/yellow leads for the brake switch you wish to test and connect the ohmmeter or continuity light across the leads. Continuity should appear when the brake lever or pedal has moved 20–30 mm (0.8–1.2 in.) measured at the tip of the lever or pedal.

The point of activation of the rear brake light switch can be adjusted by loosening the plastic locknut and moving the switch up or down on its brake (down to allow the switch to come on later, and vice versa). However, if continuity cannot be

established, the switch should be replaced.

HORN SWITCH

Remove the headlight and disconnect the light green and the green wires in the headlight case. Check for continuity across them when the horn button is pushed. If continuity is not established when pushing the horn button, the switch is defective and should be replaced.

HEADLIGHT SWITCH

Disconnect the four headlight switch leads inside the headlight case. Check for continuity across them (on the switch side) when the switch is off. There should be no continuity.

Turn the headlight switch on and check again for continuity. It should exist for all four wires. If it does not, the headlight switch is defective and should be replaced.

The four headlight switch wires are color-coded: black, brown/white, blue/white, and white/yellow.

HEADLIGHT DIMMER SWITCH

Disconnect the dimmer switch leads inside the headlight case. They are: blue/white, blue, and white. Check for continuity between the wires on the switch side as the switch is moved to each of its positions.

When the switch is in the middle, there should be continuity between all three.

When the switch is in the "Hi" position, continuity should exist between the blue/white and blue wires, but not between either of these two wires and the white lead.

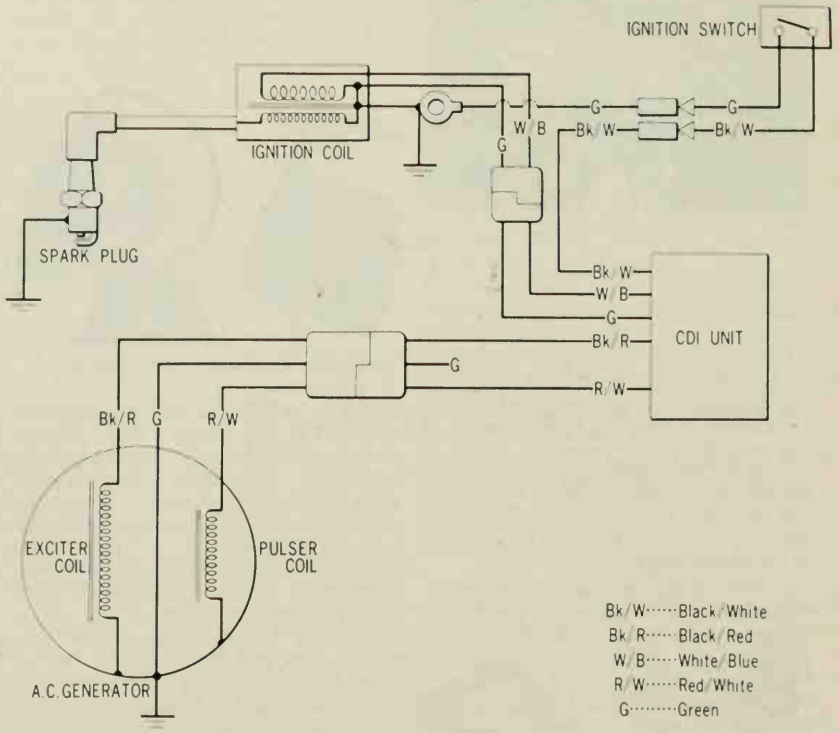
When the siwtch is on the "Lo" position, there should be continuity between the blue/white and the white leads, but not between either of these and the blue wire.

TURN SIGNAL SWITCH

Disconnect the gray, light blue, and orange leads inside the headlight case and check for continuity between them as the turn signal switch is turned to the "R" and "L" positions.

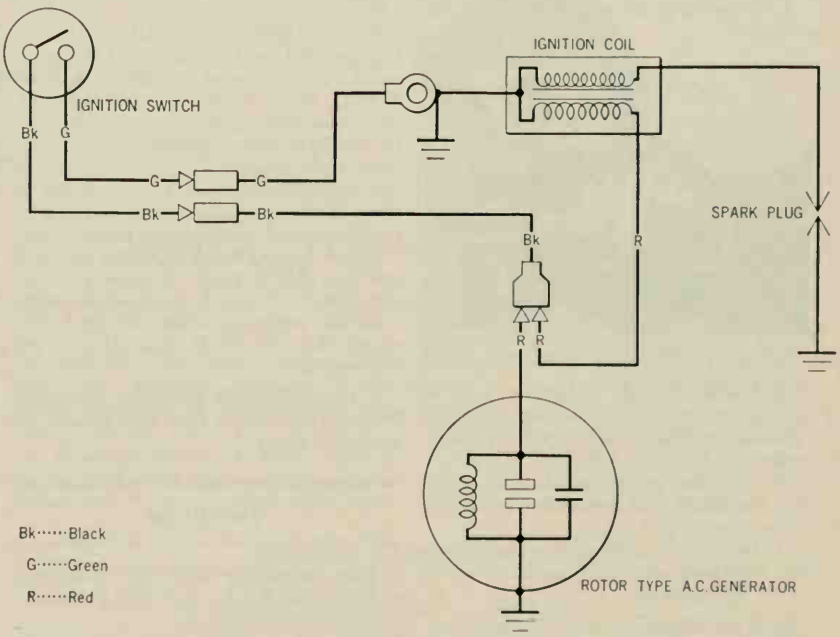
When the switch is in the middle position, there should be no continuity between any of the wires.

When the switch is turned to "R," there should be continuity between the gray and light blue wires only.



When the switch is turned to "L" there should be continuity between the gray and orange wires only.

If continuity exists where it is not supposed to or does not exist in all of the above cases, replace the switch.



NEUTRAL SWITCH

Remove the left sidecover to gain access to the neutral switch. Use the continuity tester or ohmmeter to check for continuity between the switch and the engine case, as shown. Continuity should exist only when the transmission is in Neutral. Otherwise, it should be replaced.

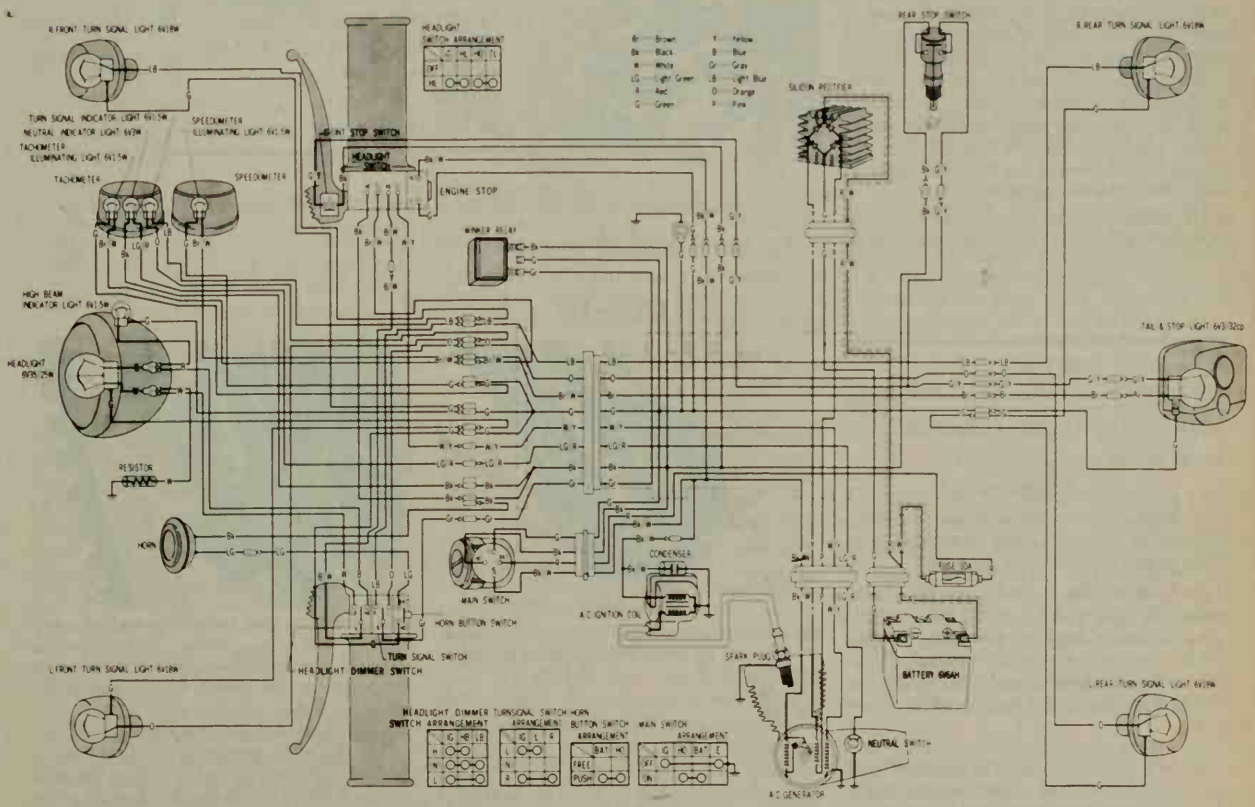
BEAM REPLACEMENT



1. The headlamp is a sealed beam unit. To replace the sealed beam, first remove the securing screws, and remove the headlamp from the case.

2. Remove the two retaining lockpins, and then the lockscrews from the headlight rim.

3. Remove the lateral adjusting screw.
4. Take the old beam out of the rim, insert the new one and replace the adjusting screw, lockscrews, and pins.
5. Adjust the headlight as directed below.

ADJUSTMENT

Set the machine about 25 feet away from and perpendicular to a wall, preferably of a color which reflects light well. The machine should be off the stand, and with a rider putting his weight on the machine as in operation. Start the engine and switch on the high beam. The headlight beam should be parallel to the ground, and should hit the wall directly in front of the machine.

If vertical adjustment is required, loosen the headlight case mounting bolts and pivot the case up or down as required.

For lateral (side) adjustment, use the phillips head screw at the right-side of the headlight.

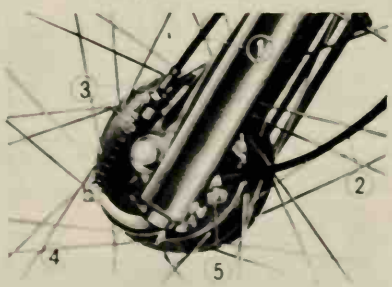
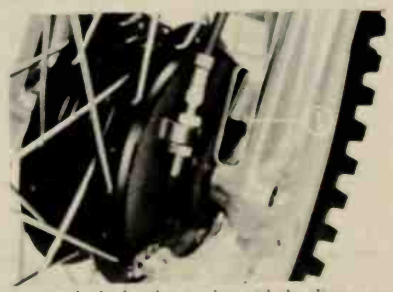
REMOVAL AND INSTALLATION



Front Wheel

125, 175 MODELS

1. Support the front wheel off the ground by placing a crate or another suitable object beneath the engine.



2. Loosen the locknut on the brake cable adjuster and run the adjuster up to give as much slack in the cable as possible. Remove the cotter pin which secures the cable end and disconnect the cable from the brake lever and the brake plate.

3. MT only: remove the phillips head screw and pull the speedometer cable from the speedometer drive housing.

Disconnect the front brake cable (1), remove the speedometer set screw and disconnect the speedometer cable (2)

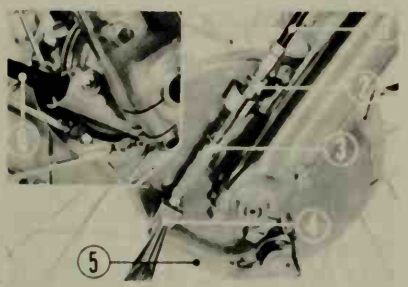
4. Remove the cotter pin from the axle and remove the axle nut and washer (a phillips head screwdriver may be placed through the left-side of the axle to keep it from turning while unscrewing the nut).

Engage the brake plate anchor with the slider upon installation

Using the screwdriver, pull the axle out and remove the front wheel assembly from the forks.

5. To install, hold the front wheel between the forks engaging the brake plate anchor with the left fork leg. Slip the axle in place from the left-side. Keeping the axle from rotating with a screwdriver, in-

stall the washer and axle nut. Torque the nut to 39.8–47.0 ft lbs then back it off until a slot in the nut lines up with a hole in the axle. Secure the axle nut with a new cotter pin.



6. Install the front brake cable to the brake lever and then to the brake plate. Secure the cable pin in place with a new cotter pin. Adjust the brake cable as outlined in "Maintenance".

7. MT only: line up the slot in the end of the speedometer cable with the tab in the speedometer drive by slowly rotating the wheel. Install the speedometer cable and secure it in place with the phillips head screw.

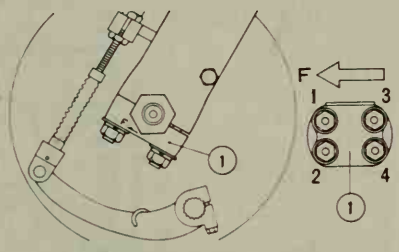
3. MT/MR only: remove the phillips head screw from the speedometer drive housing and disconnect the speedometer cable.

4. Remove the eight axle cap nuts (four on each fork leg).

NOTE: *Before removing the nuts, place a block of wood under the tire to keep the weight of the wheel off the axle caps as the nuts are loosened.*



5. Remove the block from under the tire, letting the axle drop below the studs on the fork legs. Remove the wheel.

6. For installation: holding the wheel in place, with the brake plate anchor engaged in the fork leg, install the axle caps with the "F" mark toward the front. Place a flat washer, lockwasher, and nut on each stud in that order. Position the speedometer drive housing so that the cable will not be excessively bent when connected.

7. Tighten the nuts, starting with the outside front; then the inside front followed by the outside rear and the inside rear. Tighten the nuts to a torque of 13.0–18.1 ft lbs.

NOTE: *When all the nuts are tightened properly the axle caps and the fork sliders should be touching in the front with a small gap in the rear.*

8. Install the front brake cable. Secure the cable to the brake lever with a new cotter pin. Adjust the cable.

Axle cap installation and nut tightening sequence

9. MT/MR only: line up the slot in the end of the speedometer cable with the tab in the speedometer drive housing by rotating the wheel slowly. Install the speedometer cable and secure it in place with the phillips head screw.

Rear Wheel

ALL MODELS

1. Raise the rear wheel off the ground by placing a crate or another suitable object under the engine.

2. Remove the cotter pin and axle nut from the left-side of the axle.

3. Remove the cotter pin, securing nut, lockwasher, and flat washer from the brake anchor at the brake plate. Disconnect the brake anchor from the brake plate.

Unbolt the rear brake anchor (1) from the brake plate (4), and disconnect the brake cable (3) from the lever (2)

4. 125, 175 cc models: loosen the cable adjuster and remove the cotter pin from the brake lever. Disconnect the brake cable from the brake lever and the brake plate.

5. 250 cc models: remove the cable adjusting nut and disconnect the cable from the brake lever and brake plate.

6. Loosen the chain adjuster locknuts and run the adjusters in. Move the wheel forward in the swing arm and slip the drive chain off the rear sprocket.

7. Pull the axle out from the right-side and remove the wheel assembly from the swing arm.

NOTE: *Place the wheel spacers on the axle in the order in which they are removed and screw the axle nut on the axle for safekeeping.*

8. To install the wheel: install the drive chain around the rear sprocket. Hold the wheel in place and slip the axle in from the right-side. Be sure that the wheel spacers are in their correct locations.

9. Engage the brake anchor with the brake plate and secure with the flat washer, lockwasher, and the nut. Install a new cotter pin in the brake anchor bolt.

10. Turn the axle nut on finger-tight. Adjust the drive chain slack; the slack, measured midway between the sprockets, should be about ¾ in. Refer to "Maintenance" if necessary.

11. 125, 175 cc models: connect the brake cable to the brake lever and brake plate. Secure the cable end pin to the lever with a new cotter pin.

12. 250 cc models: install the cable pin in the brake lever. Slip the cable through the pin and screw the adjusting nut on.

13. Tighten the axle nut to the proper torque of 43.4–57.9 ft lbs for MT and MR models; 50.6–65.1 ft lbs for the CR125 and 57.9–72.3 ft lbs for the CR250. Then back it off until a slot in the nut is lined up with a hole in the axle. Secure in place with a new cotter pin.

14. Adjust the rear brake cable as described in the "Maintenance" section. Check chain for proper slack.

INSPECTION (ALL MODELS)

Brakes

1. Clean all parts thoroughly with a suitable solvent, making a special effort to remove the dust and built-up dirt from the backing plate.

2. Inspect the shoes for wear. There should be at least 0.10 in. (2.5 mm) of lining material left (measured at the lining's thinnest point) or the shoes must be replaced.

3. Inspect the linings for scoring or grooves. These may be caused by particles of dirt which enter the drum. If badly scored, the shoes should be replaced. If scoring of the shoes is evident, it would be wise to inspect the brake drum for the same type of damage.

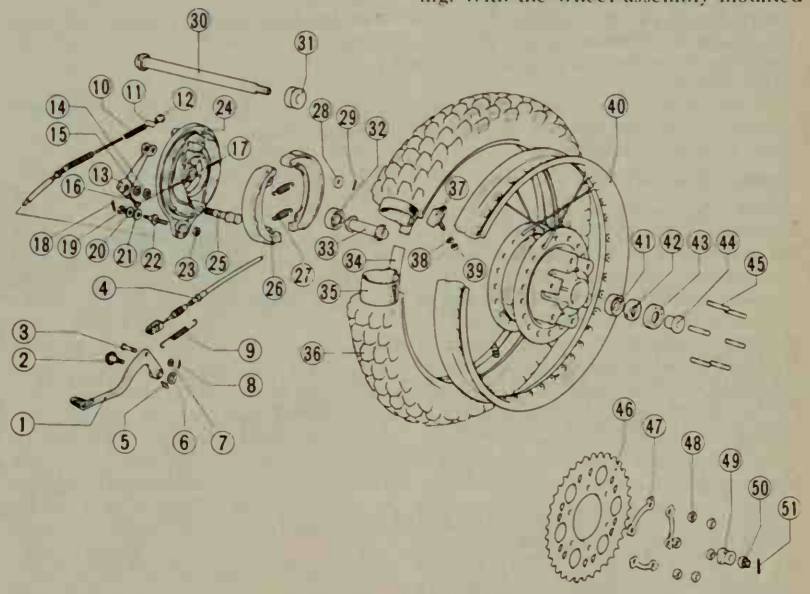
Be sure that there is no oil or grease present on the linings. Impregnated linings must be replaced.

4. If the linings are in usable condition, rough up the surface with sandpaper. Then, clean the linings thoroughly with alcohol, or lacquer thinner. Clean the brake drum with the same solvent.

5. Check that the brake lever bolt is not bent. Replace it if this has occurred. Replace the brake lever if the splines are worn or broken.

6. Inspect the splines on the brake cam. These should be in good condition. The cam must rotate freely in its backing plate passage. If it does not do so, use a fine grade of sandpaper on both the cam shaft and the surface of the passage.

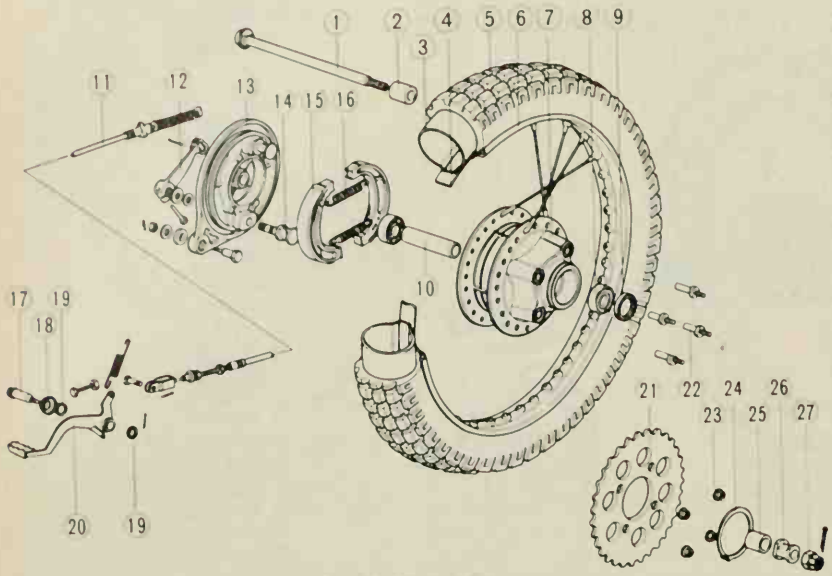
7. Check the backing plate for cracks or fractures, and replace as necessary.



Brake Drums

1. Upon disassembly of the hub, inspect the brake drum surface for condition. The drums must be clean and free from score marks or rust.

2. Rust can be removed from the drum surface with sandpaper. Polish the surface until it is shiny, then clean it thoroughly.



3. Alcohol or lacquer thinner can be used to remove dirt or deposits from the drum.

4. The drum should be checked for concentricity. An out-of-round condition is usually noticeable as an on-off-on feeling when the brake is applied while riding. With the wheel assembly mounted

on the machine, spin the wheel while applying the brake very lightly. The rubbing noise of the brakes against the drum should be heard for the entire revolution of the wheel.

5. An out-of-round condition and most scoring can be removed by having the drum turned on a lathe.

Cushion Hub (MT250)

When the sprocket and drive flange are removed, check the condition of the rubber cushions in the hub. Replace them if they are worn, cracked, or hardened. The cushions must not allow the drive flange to move more than ½ in. in the hub. This reading is taken by placing the flange in the hub and noting the total movement of the rim of the flange relative to the rim of the hub in the plane of wheel rotation. If movement exceeds ½ in., the cushions should be replaced.

Wheel Bearings

1. Clean the bearings, washers and spacer tube in a suitable solvent, removing all of the old grease. At this point, it would be wise to clean out the hub as well.

2. Check the bearing bosses in the hub for scuffs, cracks, or distortion. If they are in any way damaged, the hub must be replaced.

3. Check the condition of the steel washers and the spacer tube, and replace if damaged.

4. Bearing condition is very important. Check the balls themselves for pitting, wear, or rust.

5. Apply a few drops of light oil to the bearing, and spin it. The bearing must rotate smoothly and freely. Any roughness or binding in rotation will necessitate a new bearing.

6. Note that bearings must be replaced in pairs.

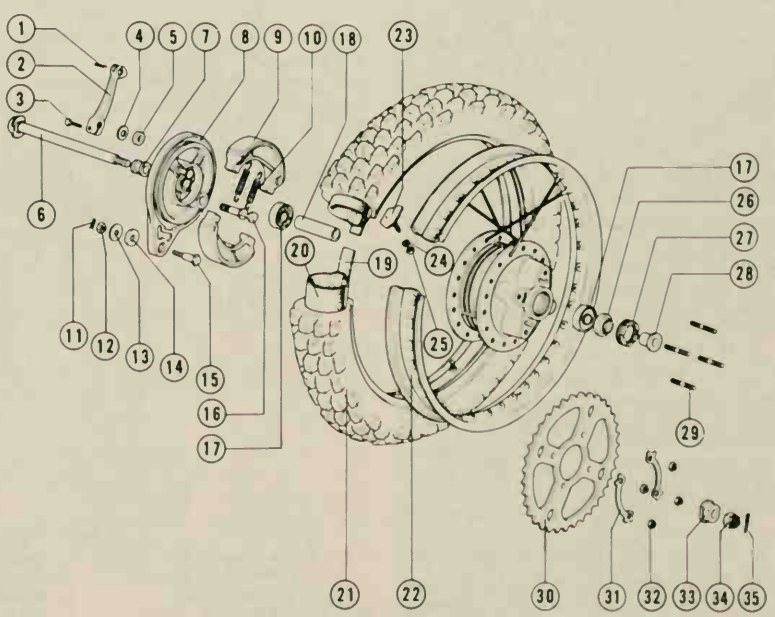
WHEEL ASSEMBLY

Assembly is in the reverse order of disassembly; however, not the following points:

1. Obtain a good grade of wheel bearing grease (such as Lithium or Moly) to lubricate the wheel bearings.

2. Pack the wheel bearings until they are completely filled.

3. Apply some grease to the inside of the hub and drive one of the wheel bearings into its seat. Install the retainer if so equipped. Install the spacer tube and drive the other bearing into its seat. The sealed surface of the wheel bearings must face the outside of the hub.



NOTE: *When a bearing retainer is fitted, the bearing closest to the retainer should be installed first. Then install and tighten the retainer, spacer and the other bearing.*

5. Coat the surface of the brake cam with chassis grease before installing it into the brake plate.

6. Lubricate the brake shoe pivot points with chassis grease. Take care not to allow any grease to come in contact with the surface of the brake shoes or drums.

7. MT models: line up the lugs on the speedometer gear with the slots in the front wheel hub.

8. Install the brake lever on the brake cam so that the punch marks on the brake cam and brake lever are lined up.

3. Remove the front wheel.

4. Loosen the pinch-bolts on the upper and lower triple clamps and remove the fork legs one at a time by pulling them straight down. If the fork legs resist removal, spread the lower triple clamp with a wedge and tap the fork leg out with a soft-faced mallet.

Fork filler caps (1), upper and lower triple clamp pinch-bolts (2), and fork tube (3)

DISASSEMBLY

The procedure is given for one fork leg, but applies to both.

1. Remove the filler cap from the top of each fork leg and pour the oil into a suitable container to be disposed of. The fork spring(s) will come out when the fork leg is turned upside down and can be removed at this time. If two springs are fitted to each leg, do not lose the washer positioned between them.

2. Turn the fork leg upside down and rest it on a block of hard wood. With an impact driver and the proper bit, remove the allen bolt from the bottom of the slider.

NOTE: *These bolts are installed with thread locking compound and trying to remove them without an impact driver will result in rounding the head of the bolt.*

3. When the bolt is removed from the bottom of the slider, the damper rod complete with piston ring, and the rebound spring can be removed by taking them out from the top of the fork leg.

4. The inner tube can now be pulled out of the slider. Once the inner tube is pulled out of the slider, the oil seal in the slider will have to be replaced.

5. Remove the dust cover and snap-ring from the top of the slider and pry out the oil seal with a hooked tool. The pin wrench from the Honda tool kit may be used by slipping the hooked end under the seal and tapping on the handle with a hammer. A strip of copper or soft metal can be placed between the top of the slider and the wrench to protect the slider.

INSPECTION

1. Wash all parts in a solvent and dry.

2. Inspect the fork slider for cracked, broken, or distorted axle brackets, worn inner bore surfaces, damaged threads, or dents which have affected the inner bore. Replace the slider if defective in any of the above ways.

3. Inspect the fork inner tubes for condition; the chrome plating must be intact throughout. Check for damaged threads and worn or scuffed inside surfaces. Check the tubes for straightness. This is done by placing the tubes in a set of V-blocks and checking the run-out with a dial gauge. If the tube is bent more than 1.5 mm (0.06 in.) as indicated by the gauge, it must be replaced.

4. Inspect the piston ring for wear or scoring.

5. Check the O-ring for cracks or any other signs of wear; replace it if damaged.

6. Check the general condition of the fork springs. Replace any that are badly rusted, have collapsed coils, etc. Compare the lengths of corresponding springs. They should be of approximately equal length. If the springs differ in length by more than ¼ in., both springs should be replaced.

7. Coat all parts with ATF before assembly.

ASSEMBLY

1. Lubricate the oil seal with ATF and install it in the top of the slider. Place a block of hard wood over the seal and drive it into the slider as far as possible. Then place the old oil seal on top of the new one and drive them in until the new seal clears the snap-ring groove in the slider. Take out the old seal. Be sure that the new seal is straight in the slider. The distance from the top of the seal to the snap-ring groove should be the same all around the seal. Install the snap-ring.

2. Fit the dust seal to the fork tube, then carefully install the slider. Install the rebound spring then the damper rod from the top of the fork tube. Refit the fork spring(s) and cap temporarily. Turn the fork upside down and install the bolt in the bottom of the slider. The threads of this bolt should be coated with thread locking compound.

3. Fit the drain plugs; be sure to install a copper washer on the drain plug.

4. Remove the cap and fill the forks with the proper amount of ATF. The specifications for your model can be found at the end of the "Maintenance" section. Refit the cap.

INSTALLATION

1. Slide the fork legs through the upper and lower triple clamps. Tighten the pinch-bolts on the lower triple clamp and then secure the fork filler caps and the pinch-bolts on the upper triple clamp.

NOTE: *On MT and CR models the front fork height is adjustable. The top of each fork leg has six grooves which are 5 mm apart. On MT models, use only the top three grooves. On both models be sure that the right and left fork legs are adjusted the same.*

On MT models, use only the top three marks

2. Install the front wheel and check the forks for smooth and proper operation.

FRONT FORK ADJUSTMENT (MT AND CR MODELS)

The height of the front forks can be adjusted to change the handling characteristics of the motorcycle. The MT models are adjustable three ways and the CR models are adjustable six ways. Raising the forks up through the triple clamps will make the motorcycle steer quicker as for low-speed riding. Lowering the forks through the triple clamps will give more high-speed stability. The procedure for adjusting the forks is as follows:

1. Loosen the pinch-bolts on the upper and lower triple clamps.

2. Raise or lower the forks to the desired position and tighten the pinch-bolts.

NOTE: *On MT models, use only the top three adjusting grooves.*

Handlebar

DISASSEMBLY

MT Models

1. Remove the two phillips head

screws from the throttle cable housing and remove the top of the housing. Disconnect the throttle cable from the twist-grip. If the throttle cable is to be replaced, disconnect the cable from the carb and oil pump. Replace the cable and route the new one as shown.

2. Remove the two phillips head screws from the headlight switch. Remove the cable ties from the handlebars and remove the switch from the bars. If the switch is to be replaced, remove the headlight lens and disconnect the leads from the wire harness.

3. Remove the turn signal/dimmer switch from the handlebars. If it is to be replaced, disconnect the leads from the wire harness inside the headlight shell.

4. Remove the phillips head screw and rear view mirror from the right handle lever bracket and remove the ignition switch from the handlebar. If the switch is to be replaced, disconnect the leads from under the fuel tank.

5. Loosen the screws securing the control lever brackets to the handlebars.

6. Remove the four handlebar mounting bolts (two on each holder), and remove the holders.

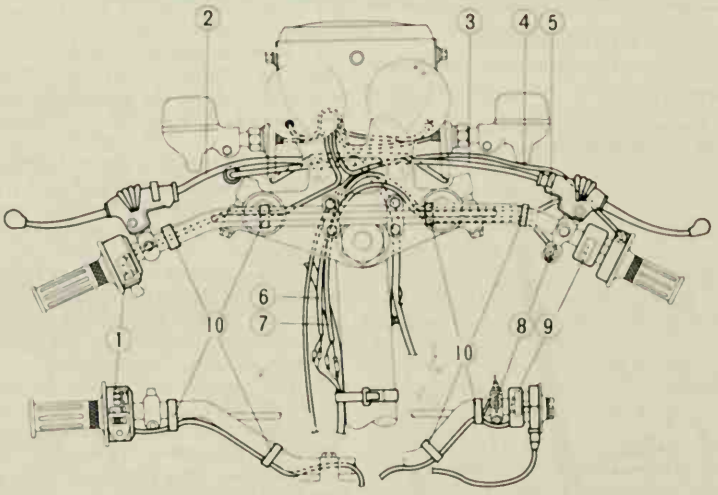
7. Lift up the handlebars and slide the control lever brackets off the handlebars. Remove the handlebars from the machine.

CR, and MR Models

1. The procedure for disassembling the handlebars on CR models is the same as for the MT models except for Step 1. The throttle cable need only be disconnected from the carb to replace it as the CR models are not equipped with an oil pump. Steps 2 and 3 may be omitted.

ASSEMBLY

All Models



Assembly is in the reverse order of disassembly; however, note the following points:

1. When installing the hand grips, coat the inside of the grips with an adhesive.

2. Place the handlebars in place on the mounts; align the punch marks located at the outside of the serrations on the handlebars with the top of the lower handlebar mounts. This will correctly center the bars.

3. The upper handlebar holders have a punch mark on the front upper surface. This mark must face the front of the motorcycle when they are installed. When tightening the mounting bolts, start with the front bolts. Tighten the bolts to a torque of 13.0–18.1 ft lbs. There should be no space between the front of the holder and top of the lower mount.

4. MT models only: when installing the headlight switch and the turn signal/dimmer switch, locate the pin on the switch into the hole in the handlebar.

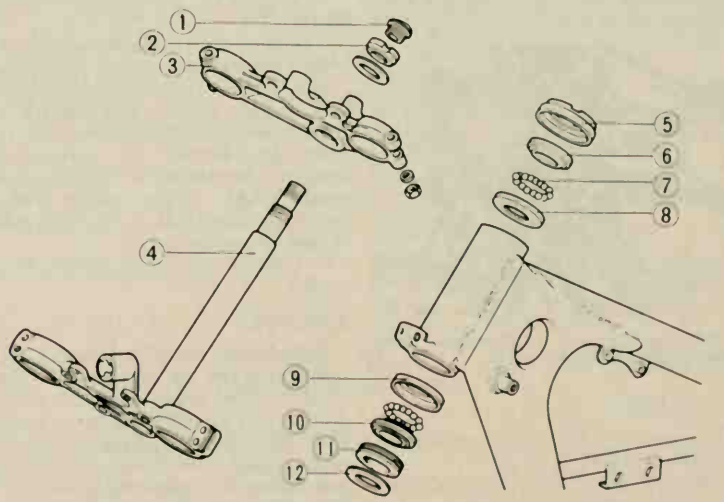
Steering Stem Assembly

BEARING ADJUSTMENT

1. The steering stem bearings are uncaged #6 (125 and 175 models) or #8 (250 models) balls. They are adjusted by means of a ring nut beneath the upper triple clamp.

2. To check bearing adjustment, support the front wheel off the ground. Grasp the fork sliders with both hands.

3. Attempt to move the forks by pulling out on the sliders. If play or movement can be felt, the bearings are too loosely adjusted or worn.



4. Turn the forks slowly from lock-to-lock. Movement should be smooth, silent, and effortless. If any binding or uneven movement is felt, the balls and races are either too tightly adjusted or are worn. If the steering feels uniformly stiff, the bearings are too tightly adjusted. If any noise is noted, the bearings are damaged or some are missing.

5. With the front wheel off the ground, release the front forks from a few degrees off the centered position. The forks should fall freely to either side of their own weight. If they will not, the bearings are too tightly adjusted, the steering stem is bent, the races are extremely worn, or some of the bearings are missing.

6. Bearings on most models can be adjusted with a hammer and punch on the adjuster nut under the upper triple clamp with the triple clamp still in place. However, the upper triple clamp pinch-bolts and steering stem nut should be loosened to allow movement of the adjusting nut.

7. Tighten or loosen the adjuster nut a little at a time until the steering stem adjustment conforms to that outlined above.

8. If proper adjustment is not possible, the bearings and races will probably need to be replaced.

REMOVAL

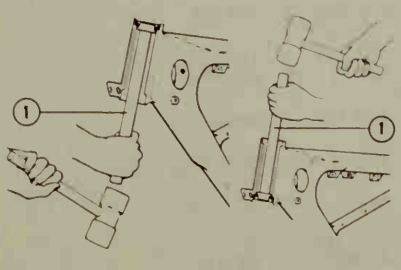
1. Remove the front wheel, front forks, fuel tank, and handlebars as described previously.

2. Disconnect the speedometer and tachometer cables (if fitted) from the instruments. Remove the headlight lens and disconnect the wire harness. Remove the two bolts which secure the headlight mounting bracket and remove the tachometer, speedometer, headlight, and headlight bracket by pulling the bracket up.

Bolts securing the headlight mounting bracket (1)

3. Remove the front fender from the steering stem by removing the four mounting bolts. Pull the gas tank breather tube out of the triple clamp.

4. Loosen the upper triple clamp pinch-bolts (3). Remove the steering stem nut and washer. Tap upward with a plastic mallet to remove the upper triple clamp.



5. Loosen the steering stem race adjuster nut with a pin wrench, then hold the steering stem up while unscrewing the adjuster nut the rest of the way off. Remove the steering stem top cone race and the ball bearings from the top race.

6. Carefully pull the steering stem out from the bottom. Some of the ball bearings from the lower race will most likely fall out at this time so be prepared for this.

7. The bottom cone race is removed from the steering stem by prying it off, if replacement is necessary.

8. The bearing races in the frame lug are a press-fit and should not be removed unless replacement is necessary. If replacement is necessary, the old races can be removed by reaching through the frame lug with a suitable punch and tapping the races out from the inside of the lug.

New races are installed using a suitable sized bushing driver: i.e., one which will drive the race squarely into its seat.

Removing the steering stem frame races with hammer and punch

Be certain that the race goes straight in.

These races can also be installed using a block of hard wood of sufficient size to cover the race in place of a bushing driver.

INSPECTION

1. Wash the bearings in a suitable solvent.

2. Clean all of the old grease from the bearing race surfaces, the steering stem, and the frame lug.

3. Inspect the bearing race surfaces. They must be clean and smooth. That is, free from any cracks, scoring, indentations or rust. Run your finger around the bearing race surfaces. Note any roughness or ripples on the race surfaces. Replace them, as a set, as necessary.

4. Check the balls themselves for rust, pitting, or flat spots. Replace the bearings as a set if any such damage occurs.

5. Check the dust seal for condition and replace if necessary.

6. Check the steering stem for cracks or a bent condition; this is especially important if the bike has been involved in a spill.

INSTALLATION

1. Install the dust seal washer, dust seal, and bottom cone race onto the steering stem. Use a good grade of bearing grease to coat the bottom cone race and the top race in the frame lug.

2. Embed the balls into the grease of the top frame lug race and the bottom cone race.

NOTE: *The 125 and 175 cc models use #6 balls: the MT125 has 18 balls in each race, while the CR125, and MR175 have 21 balls in each race. The 250 cc models use #8 balls with 18 balls in each race for both models.*

3. When the balls are in place, slip the steering stem through the frame lug and hold it in place, while refitting the top cone race and threading on the adjuster nut.

4. Tighten the adjuster nut all the way, then back it off until the steering stem turns with ease, but has no play.

5. Install the upper triple clamp and the fork tubes. Check that the stem will fall to either lock freely of its own weight when released from 5–10° off center; if not check for:

a. Steering bearing too tight;
b. Bent steering stem;
c. Worn races or balls.

6. Install the flat washer, steering stem nut, and steering stem rubber cap.

7. Install the front wheel, front fender, headlight bracket, handlebars, and fuel tank.

Rear Shock Absorbers

No service to the rear shocks is possible. In the event of oil leaks, bent or broken plunger shaft, dented or otherwise damaged case, or worn mounting bushings, the shock absorber must be replaced.

If the shock absorbers are somewhat old, and one fails in the course of normal usage (such as an oil leak) it would be a good idea to replace both shocks to insure equal damping characteristics.

To check a shock which is removed from the machine, place the bottom end on the ground and use the weight of your body to compress it as much as possible. Release the shock and note the rebound behavior. If the shock returns quickly at first, then slowly returns to the normal length, it is serviceable. If it returns to its normal length all at once, it should be replaced.

Swing Arm

ALL MODELS

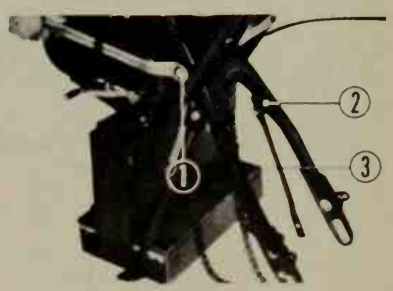
Inspection

1. Disconnect the chain. Remove the rear wheel and sprocket assembly.

2. Remove the shock absorbers and chain guard.

3. Measure the distance between the top and bottom shock absorber mounts on both sides. The two measurements must be identical, or the swing arm will have to be replaced or fixed.

4. Check that the rear wheel mounting plates are parallel.



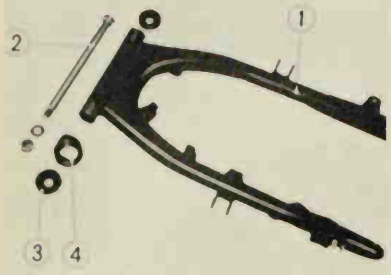
5. Grasp the legs of the swing arm and attempt to move it from side-to-side. Any noticeable side-play will indicate that the swing arm bushings in the frame need replacement.

The swing arm is most likely to be damaged if the machine is operated for any length of time with a broken or otherwise defective shock absorber.

Removal

1. Proceed as above. Then remove the swing arm pivot bolt nut, and pull out the pivot bolt.

2. Remove the swing arm.



Removing the swing arm pivot bolt nut

3. The swing arm should be inspected for cracks or fractures, especially around the welds.

After removal of the swing arm, the dust seals and bushings can be replaced. This should be done every 10,000 miles, or more often depending on how the machine is used, or if the bushings are worn (see "Inspection," above).

4. Remove the bushings, tapping them out with a punch and hammer. Once bushings are removed they should be replaced. Remove the spacer as well.

Swing arm assembly: swing arm (1), swing arm pivot bolt (2), dust seal (3), and chain protector (4)

5. Lubricate new bushings and both the inside and outside of the spacer with a good chassis grease. Press in one bushing, refit the spacer, and install the other bushing.

6. Install the swing arm on the machine. After tightening the swing arm pivot shaft nut, move the swing arm up and down to ensure that movement is smooth and effortless.

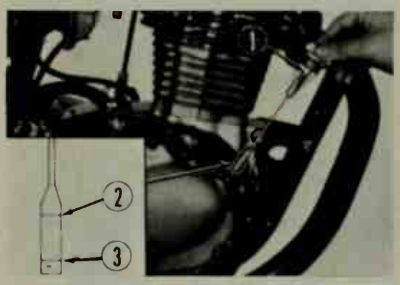
Maintenance



NOTE: *Common maintenance procedures are explained in detail in "General Information."*

Oil Changes and Lubrication

CHECKING OIL

On all models the oil level is checked by means of the dipstick incorporated into the filler cap. The filler cap is located in the right crankcase cover. To check the oil:

1. Start the engine and allow it to warm up for a few minutes.
2. Hold the motorcycle upright on level ground, remove the dipstick and wipe it clean.
3. Reinsert the dipstick, allowing the dipstick cap to rest on the top of the threads of its hole. The oil level should be between the maximum and minimum marks on the dipstick. If the level is below the minimum mark on the dipstick add enough oil through the hole to bring the level up to the maximum mark.

Checking oil level: the dipstick should rest on the top of the hole. Level should be between the maximum and minimum marks (2 and 3)

CHANGING OIL

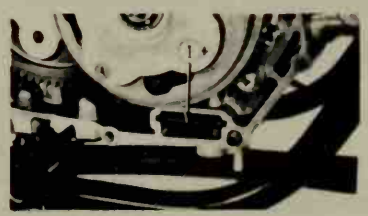
Change the oil at least every 1,500 miles under normal operating conditions.

NOTE: *If the motorcycle is used under severe conditions (i.e., racing, high-speed operation, stop-and-go riding, dusty conditions, operation in cold weather, etc.), changes should be made more frequently. This is also true if the machine is used infrequently especially during winter months.*

1. Allow the engine to run for a few minutes until it is close to operating temperature.
2. Remove the dipstick, then place a pan under the engine to catch the oil. Remove the drain plug from the sump, and allow a few minutes for the oil to drain, then kick the engine over a few times with the kick-starter to remove any oil remaining in the delivery system.
3. XL175 only: When the drain plug is removed, the screen-type filter and filter spring will come out. Clean the filter in solvent, and inspect it for any puncture holes.
4. Refit the drain plug (and filter spring and screen on the XL175) and fill the sump with the correct amount and grade of oil. Refer to the charts at the end of this section. Run the engine for a minute or two. Then shut it off let it sit for one minute and recheck the oil level; add oil as necessary until the level is correct.

Removing the filter and filter spring (175)

NOTE: *SAE 10W-40 or 10W-30 is recommended for all models. Use only high grade, detergent motor oils service rated "SE." The use of oil additives is not recommended as they may cause clutch slippage.*



OIL FILTER

Filter service is required at least every fourth oil change, or once per year.

Two types of oil filters are used on XL series Hondas; an oil filter screen and a centrifugal oil filter. The centrifugal oil filter is located on the right end of the crankshaft (except on the XL 70 which uses the center of the clutch outer housing as the filter). The filter screen on XL350 and XL250 models is located at the bottom rear of the right crankcase cover. On the XL175 the filter screen is directly above the drain plug. The XL125 and XL100 have the filter screen in the left-side of the sump while the XL70 has a screen plate in the right crankcase half under the right crankcase cover.

Oil Filter Screen

1. Drain the oil as previously described.
2. Remove the oil filter screen cap (except XL70).
3. Withdraw the filter spring and filter screen.
4. XL70 only: Remove the footrests, kick-starter lever, and the right crankcase cover. Remove the filter screen from the lower portion of the crankcase.

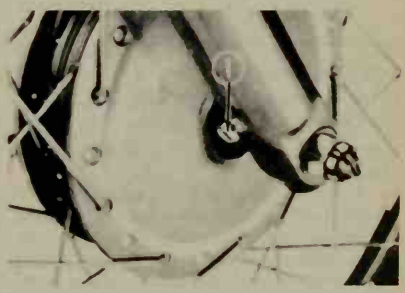
Oil filter screen location (XL70)

Spring and screen filter location (125/100 shown)

5. Wash the filter screen in solvent and inspect it for any punctures.
6. Installation is the reverse of the above.

Centrifugal Oil Filter

ALL EXCEPT XL70



1. Drain the oil as described above.
2. Remove the kick-starter lever and right footrest. Remove the right crankcase cover.
3. Remove the snap-ring or three screws from the oil filter cap and remove it.
4. Wipe the inside of the filter rotor with a clean rag to remove any deposits.
5. Inspect the O-ring for any nicks or cracks, replace if damaged in any way.
6. Line up the tabs on the filter cap with the slots in the rotor and push the end plate into the rotor. Secure with the snap-ring or three screws on the XL125/100.

XL70

1. Drain the oil, remove the kick-starter, footrests, and right crankcase cover.
2. Unscrew the four securing screws from the clutch outer cover, and remove the cover.
3. Wipe the inside of the clutch outer housing with a clean rag to remove any dirt or metal chips.
4. Install the clutch outer housing cover and tighten the four securing screws.
5. Inspect the right crankcase cover gasket and replace it if it is damaged in any way. Install the right crankcase cover, footrests and kick-starter. Refill the engine with oil.

FRONT FORKS

1. ATF is recommended for the front forks. If slightly stiffer damping characteristics are desired use SAE 30 oil.

Fork drain plug location (1)

2. Fork oil should be changed every 6,000 miles or once every 12 months.
3. To drain the fork oil, remove the drain plug at the lower portion of one of the fork sliders. Allow the oil to drain for several minutes into a suitable container, pumping the slider up and down several times. After most of the oil is expelled, turn the forks all the way to the right to completely drain the right fork leg, or to the left for the left fork leg. Check the condition of the drain plug gasket. Replace it if necessary. Refit and tighten the drain plug.

4. Repeat the procedure with the other fork leg.

5. Support the front wheel off the ground. Remove the fork filler cap from each fork leg. The handlebar clamps may have to be removed and the handlebars pulled back to allow access to the fork caps. Loosening the upper triple clamp pinch-bolts may make removal easier.

6. Add the correct quantity of ATF to each fork leg. Capacities for each model are given in the chart at the end of this section.

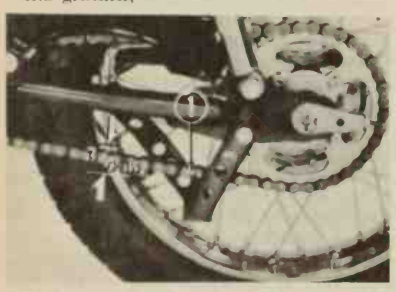
NOTE: *Fork oil should be accurately measured, and added slowly. Both of these aims can be accomplished by using a baby bottle with the rubber nipple cut off to add oil to the forks. These are usually calibrated in cubic centimeters or ounces. On 100 cc and larger bikes, the spring can be taken out, if necessary, to facilitate the addition of the oil.*

7. Inspect the condition of the fork filler cap O-ring, and replace it if it is torn or cracked. Fit the caps and tighten them securely. Tighten the handlebars and pinch-bolts if they were loosened. Allow a moment for the oil to settle in the forks before operation.

8. After several miles of operation, check the area around the fork slider seals for leaks or seepage. Even a minimal amount would necessitate replacement of the seals. A coating of grime building up in this area over a period of time is also indicative of ineffective seals.

CHASSIS LUBRICATION

1. The swing arm pivot on some models is fitted with a grease nipple. This item should be lubricated with a good grade of chassis grease every 3,000 miles. Grease should be applied until some of it shows at either end of the swing arm.



Service Checks and Adjustments

DRIVE CHAIN

1. The chain should have about ¾ in. (20 mm) of total up-and-down free-play measured in the middle of the lower chain run.

2. Before checking or adjusting the chain slack, the following conditions should be met:

a. A support should be placed under the engine so that the rear wheel is off the ground;

Chain free-play should be about ¾ in. measured in the middle of the lower chain run

b. The transmission should be placed in Neutral;

c. The chain should be clean and well lubricated;

d. The chain should have been checked for any tight spots by slowly rotating the wheel and checking for variances in the chain tension. If a tight spot exists, the chain tension should be adjusted to the prescribed free-play at the tight spot. Note, however, that such a condition is indicative of a worn chain and probably sprockets which should be replaced as soon as possible.

3. To adjust the chain, first back off the rear brake adjuster nut if a rod-operated brake is fitted.

4. Remove the axle nut cotter pin and loosen the axle nut several turns. Loosen the locknut on each chain adjuster bolt.

5. Turn each of the adjuster bolts or nuts in or out by equal amounts until the chain tension is approximately correct.

6. Check wheel alignment by means of the aligning marks inscribed on both sides of the swing arm. Be sure that both adjusters are lined up with the same mark on each side. If not, turn one of the adjuster bolts or nuts in or out so that alignment is achieved.

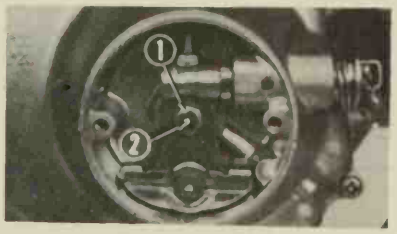
7. Tighten the axle nut and check the chain tension. Correct if necessary. After adjustment is correct, tighten the axle nut to the proper torque. Fit a new cotter pin and tighten the adjuster locknuts.

NOTE: *With a standard chain fitted, if it is necessary to move the axle beyond the fifth adjustment mark on the swing arm, the chain is worn to the replacement limit.*

8. Check the condition of the drive chain protector. If the protector has been bent, straighten it so that the chain runs through the center.

CLUTCH

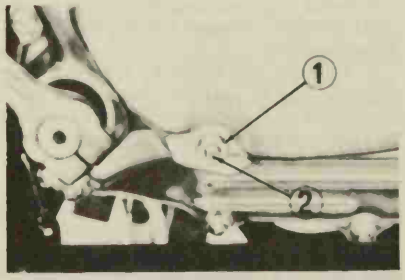
Two adjustments are made to the clutch: cable adjustment and pushrod adjustment. Usually the pushrod need not be adjusted unless the clutch malfunctions. Cable adjustment must always be maintained at the proper specification.



All Except XL175 and XL125/100(76)

Before adjusting the clutch, the cable should be well lubricated.

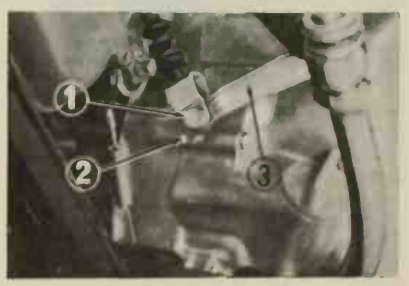
1. The clutch lever should be able to be moved 10–20 mm (0.4–0.8 in.) measured at the tip of the lever before the clutch begins to disengage.



2. To adjust the clutch, loosen the locknut on the handlebar adjuster and screw the adjuster into the lever housing to give as much slack in the cable as possible.

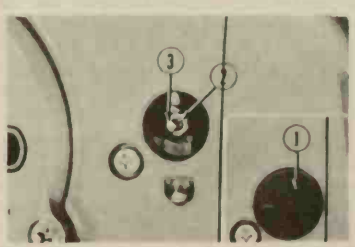
3. On 350 and 250 models, remove the rubber plug from the left crankcase cover. On the XL70 removing the chrome cover from the right crankcase cover will expose the pushrod adjuster. The pushrod adjuster on 100 and 125 models is located in the right crankcase cover near the kick-start lever.

To adjust the clutch, loosen the locknut (1) and turn the adjusting screw in until resistance is felt, then back it out ¼ turn and secure the locknut (XL70)



4. Loosen the locknut on the pushrod adjuster and screw the adjusting screw in until resistance is felt, then back it out ½–1 turn for 350 and 250 models, ⅛–¼ turn for 125 models, and ¼ turn on the XL70.

Clutch adjuster location (125/100, 1975 and earlier)



On the XL100, use the adjusting screw to align the center of the clutch lever with the mark on the crankcase.

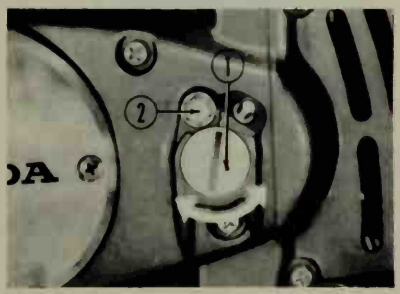
Tighten the adjusting screw locknut.

On the XL100, use the clutch adjusting screw to align the center of the clutch lever with the mark on the crankcase

5. Adjust the cable free-play so that there is 10–20 mm (0.4–0.8 in.) free-play measured at the tip of the lever. This can be done with either the handlebar adjuster or the lower cable adjuster; however any major adjustments, such as

On 350/250 models, the adjusting screw and locknut (2 and 3) are covered by a rubber plug which should be installed with the arrow indicating the front of the engine

when a new cable is fitted, should be done at the lower adjuster.



6. Install the chrome cover (XL70) or rubber plug. When fitting the rubber plug note that the arrow on the plug must point to the punch mark on the left crankcase cover.

XL175 and XL125/100(76)

Before adjusting the clutch, apply a few shots of chassis grease to the adjuster grease fitting and operate the clutch lever a few times to distribute the grease. The clutch cable should also be well lubricated.

1. The clutch cable should be adjusted so that there is 10–20 mm (0.4–0.8 in.) of free-play measured at the clutch lever tip.

2. To adjust the clutch, loosen the lockbolt above the clutch adjuster on the crankcase cover and turn the adjuster clockwise to decrease the play and counterclockwise to increase free-play. When the adjustment is correct tighten the lockbolt.

On the 175, loosen the lockbolt (2) and turn the adjuster (1) clockwise to decrease cable free-play, or counterclockwise to increase it

3. Minor adjustments can be made at either the cable adjuster on the handlebars or the lower cable adjuster located on the left crankcase cover.

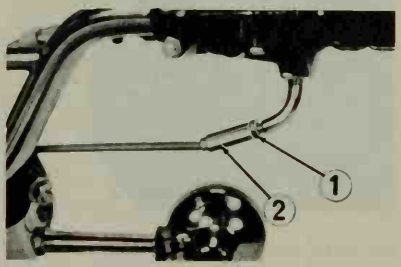
THROTTLE CABLE

The throttle cable free-play should be adjusted *after* the idle speed. This procedure is given in the "Tune-Up" section. The standard throttle cable free-play is 10–15° of grip rotation for all models.

XL350/250

1. Loosen the locknut on the cable adjuster located near the twist-grip and screw the adjuster in to give the maximum amount of free-play.

2. Loosen the locknut on the lower adjuster. Turn the adjuster until there is approximately 10–15° of play at the twist-grip then tighten the locknut.



Throttle cable adjuster locknuts (3 and 5) at the carburetor (350/250)

3. Fine adjustment is accomplished with the adjuster near the twist-grip. Be sure to tighten all locknuts when the adjustment is correct.

Other Models

1. The throttle cable free-play can be adjusted with either the upper adjuster

Throttle cable adjuster (2) and locknut (1) at the twist-grip

(near the twist-grip) or the lower adjuster located on the top of the carburetor. It is preferable, however, to turn out each adjuster a little way rather than have one of the adjusters turned out to its limit. When the adjustment is complete tighten all locknuts and slip the rubber boot over the lower adjuster.

Cable adjuster (3) on the carburetor cap

BRAKES

When the linings contact the drum, the angle formed by the brake plate lever and its cable or rod should not exceed 90°. If it is impossible to obtain the correct adjustment, the lining thickness should be checked.

Front Brake

1. Use the cable adjuster on the brake plate to allow about 20–30 mm (0.8–1.2 in.) of handlebar lever free-play before the shoes contact the drum. This free-play is measured at the tip of the lever.

2. This free-play can be maintained as the shoes wear by using the adjuster at the handlebar lever.

Rear Brake

Use the adjusting nut on the end of the cable or rod so that the brake pedal has 25 mm (1 in.) of free-play before the shoes contact the drum.

NOTE: *Some models are equipped with brake wear indicators. If the indicator marks align when the brake is fully applied, the linings should be replaced.*

Brake Light Switches

The switches should be checked for operation after the brakes are adjusted. The rear brake light switch is mounted in a slotted bracket and secured by locknuts. Moving the switch up on the bracket allows the brake light to turn on sooner. Moving it down allows the light to turn on later. Generally, the brake light should come on just as the linings contact the drum.

STEERING STEM BEARINGS

The steering stem bearings should be checked periodically and adjusted if necessary.

Grasp the fork sliders (with the front wheel supported off the ground) and pull them straight out. No play should be felt. If play is evident or if the bearings bind or make noise when the forks are turned, adjustment and lubrication are needed.

Refer to the "Chassis" section.

Fuel System

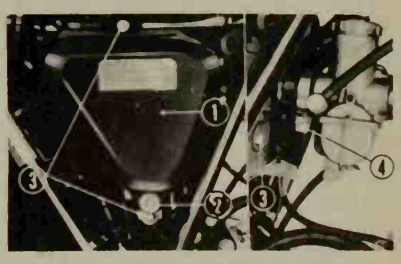
1. Fuel system maintenance involves cleaning the petcock and filter, cleaning or replacing the air cleaner, and cleaning the carburetor.

2. The carburetor should be removed, disassembled, and cleaned every 4,000 miles. The procedures are outlined in the "Fuel Systems" section.

3. The petcock should be serviced every 3,000 miles. Shut the fuel off, then unscrew and remove the petcock sediment bowl and O-ring. Take out the fuel filter screen. Clean the parts in solvent and inspect the screen for any holes or other defects, replace it if it is damaged in any way. Inspect the O-ring for any cuts or cracks and replace it if necessary. Reinstall the filter screen, O-ring, and sediment bowl. Turn the fuel on and check for leaks.

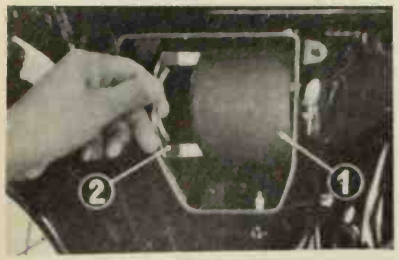
AIR CLEANER SERVICE

The air cleaner should be serviced or replaced every 1,500 miles or more often depending on conditions.



Removal

XL350/250

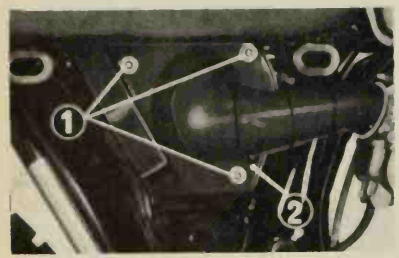


1. Remove the air cleaner cover, then remove the mounting bolt from the element, loosen the clamp, and remove the element.

XL175

1. Remove the nut securing the air filter case to the motorcycle. Remove the three bolts from the air filter and loosen the clamp connecting the air filter to the carburetor. Push the air filter forward when removing the air filter case, then remove the air filter element.

Air cleaner case (1) mounting nut (2), filter bolts (3) and clamp screw (4) (XL175)



Removing the air cleaner element retainer (XL125)

XL125

1. Remove the right sidecover.
2. Remove the three mounting nuts from the air cleaner case cover and remove the cover.
3. Remove the retainer and take out the air filter element.

XL100

1. Remove the right sidecover.
2. Remove the three mounting bolts from the air cleaner, and move the spring clamp connecting the air cleaner to the carburetor. Remove the air cleaner.
3. Remove the nut from the center of the air cleaner and remove the element.

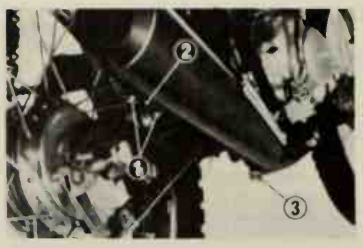
Air cleaner case mounting bolts (1) (XL100)

XL70

1. Remove the right sidecover from the air cleaner case and withdraw the filter element.

Cleaning (All Models)

1. Once the element is removed it should be cleaned in a clean solvent such as kerosene. Dry thoroughly.
2. Soak the element in gear oil (SAE 80 or 90) until it is fully saturated then wring out the excess oil.
3. Install the air cleaner in the reverse order of removal.

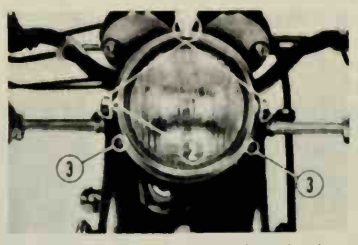


Decarbonization

The spark arrestor on models so equipped should be removed and cleaned every 1,500 miles. This should be done when the engine is cold.

1. Remove the bolt(s) which secure the spark arrestor to the end of the exhaust pipe. Grasp the spark arrestor with large pliers and pull it out. On the early XL125, remove the cover plate and the drain plug from the exhaust pipe.
2. Heat the spark arrestor with a propane torch until it is quite hot. Grasping the arrestor with large pliers, tap it against a wooden block to knock off carbon particles. When it cools, remove the rest of the deposits with a stiff wire brush and solvent.

Remove the bolt (1) and pull out the spark arrestor (2)



Remove the arrestor cover plate (2) which is secured by the two bolts (1); remove the drain plug (3) (XL125)

3. Before replacing the arrestor, start the engine and after giving it a few moments to warm up, rev the engine to remove carbon built up in the muffler. This should be done in a well-ventilated area away from any combustible materials. On the early XL125, block the end of the muffler with a rag to allow exhaust pressure to blow out the cover plate port.

HEADLIGHT ADJUSTMENT

Set the machine about 25 feet away from and perpendicular to a wall, preferably of a color which reflects light well. The machine should be off the stand, and with a rider putting his weight on the machine as in operation. Start the engine and switch on the high beam. The headlight beam should be parallel to the ground, and should hit the wall directly in front of the machine.

Vertical adjustment is made by loosening the two headlight mounting bolts slightly and pivoting the headlight up or down.

Headlight mounting bolts (1), lateral adjusting screw (2), and rim mounting screws (3)

Lateral adjustment is made by means of the phillips screw on the right-side of the headlight. Turning the screw clockwise will move the beam to the left and vice versa.

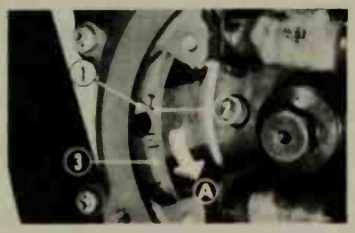
Tune-Up

NOTE: *Common tune-up procedures are explained in detail in "General Information."*

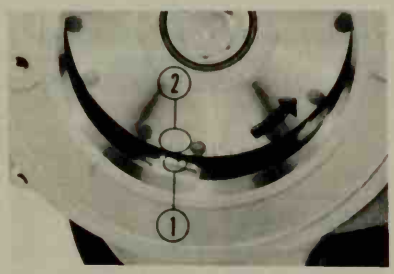
Cam Chain Adjustment

XL350/250/175

1. The cam chain adjuster and locknut are located toward the bottom of the left crankcase cover and are accessible after removing the rubber plug.
2. Remove the intake valve cap and the alternator rotor cover.



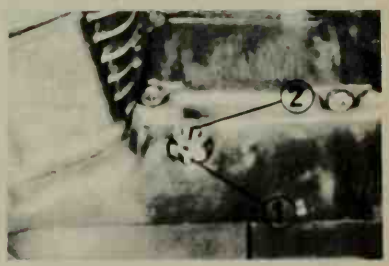
The cam chain adjuster (5) and locknut (4) are covered with a rubber cap (6) on 175–350 models



3. The piston must be positioned at TDC on the compression stroke. To do this, turn the engine over slowly in the normal rotational direction (counterclockwise) until the intake rocker arm goes down and begins to come up.

4. Continue turning the engine over until the "T" mark on the rotor aligns with the stationary mark on the crankcase cover. At this point, the piston is at TDC, compression stroke.

5. Loosen the cam chain adjuster locknut. Holding the rotor in position with a wrench on the rotor nut, loosen the cam chain adjuster. As this is done, the spring-loaded tensioner will automatically take up the slack in the cam chain. Tighten the adjuster, then the adjuster locknut.



Turn the crankshaft in the normal direction of rotation (A) until the "T" mark on the rotor (2) is aligned with the stationary timing mark (1). The piston must be on the compression stroke

Timing marks aligned (175)

XL125/100 (1975 AND EARLIER)

1. The cam chain adjuster and locknut are located on the top of the crankcase behind and to the left of the cylinder.
2. With the engine idling, note the indication of chain noise. Chattering will indicate that the chain is too loose; while a whining means that it is too tight.
3. With the engine idling, loosen the adjuster locknut, and turn the adjuster counterclockwise to take up chain slack. Turn the adjuster to a point where the chain is operating quietly. It should not be necessary to turn the adjuster very much.
4. Tighten the adjuster locknut.
5. If the adjuster is turned too far, the chain will be too tight and will begin to whine.

Cam chain adjuster (2) and the locknut (1) (125/100, 1975 and earlier)

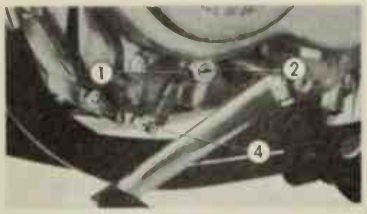
XL125/100 (76)

1. The cam chain adjuster is located on the top of the crankcase, behind and to the left of the cylinder.
2. With the engine idling, loosen the large adjuster bolt, then tighten.

Tension will be set automatically as this is done.

NOTE: *Loosen the large adjuster bolt only. Do not loosen the 6 x 10 mm bolt fitted into the top of the adjuster bolt.*

XL70



1. Cam chain adjustment is made with the engine idling. The adjustments can be made in two ways: either with the adjusting screw or with the tensioner bolt.

The adjusting screw locks the spring-loaded tensioner rod in place, and loosening it will allow tension to be automatically taken up.

The tensioner bolt allows the tensioner rod to be moved, compressing the tensioner itself.

The adjusting screw is located at the bottom of the left crankcase cover. The tensioner bolt is just below the adjusting screw, beneath a cover bolt.

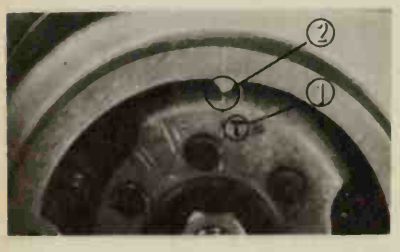
2. With the engine idling, loosen the adjusting screw locknut and back the screw off (counterclockwise) about ½ turn. Tighten the adjusting screw. If chain operation is now quiet, tighten the adjusting screw locknut, since the adjust-

Locknut (1), adjusting screw (2), and tensioner cover bolt (4) (XL70)

ment is now complete. If chain operation is still noisy, proceed as follows:

3. Remove the tensioner cover bolt. Loosen the adjusting screw locknut and back off the adjusting screw about ½ turn.

4. Turn the tensioner bolt in or out slowly until proper chain operation is obtained. If the chain chatters, it is too loose and the tensioner bolt should be turned clockwise; if the chain whines, it is too tight, and the tensioner bolt should be turned counterclockwise.



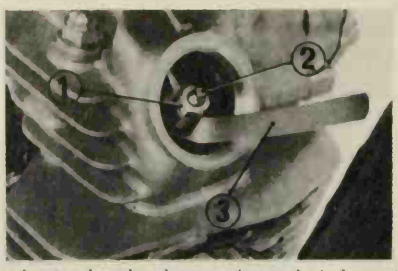
5. When chain operation is quiet, replace the cover bolt, tighten the adjusting screw and the adjusting screw locknut. Adjustment is now complete.

Valve Adjustment

ALL MODELS

NOTE: *Valves must be adjusted when the engine is cold.*

1. Remove the alternator rotor cover. Remove the gas tank (except XL70), and the intake and exhaust valve adjuster caps. Remove the spark plug.



Timing marks aligned for cam chain adjustment (XL70)

2. Position the piston at top dead center on the compression stroke by turning the engine over slowly in the normal direction of rotation (the rotor will turn counterclockwise) until the intake valve rocker arm goes down and begins to come up.

3. Continue turning the engine over until the "T" mark on the rotor is aligned with the stationary mark on the crankcase cover. The piston is now at TDC, and the valves are closed. To be sure, check for clearance at the valves. The rocker arms should have a slight amount of free-play which can be felt by attempting to move them up and down.

4. Refer to the "Tune-Up Specifications" chart at the end of this section to determine the correct valve clearance for your machine.

Adjusting the valve clearance: loosen the locknut (1) and turn the adjuster (2) until the feeler gauge (3) is a light slip fit between the adjuster and the valve stem

5. Slip the correct feeler gauge blade between the valve stem and the rocker arm adjuster. The feeler gauge should be a slip fit (a light drag) in a correctly adjusted valve.

6. If adjustment is necessary, loosen the adjuster locknut and turn the adjuster to effect proper adjustment. Tighten the locknut.

NOTE: *The adjustment may change when the locknut is tightened. Hold the adjuster steady while securing the nut. Recheck the clearance afterward.*

7. Repeat the procedure at the other valve. On the 4-valve models (XL350/250), care should be taken to make the clearances at each pair of valves as equal as possible.

Contact Breaker Points

LOCATION

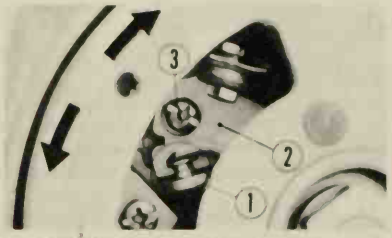
1. On all models, with the exception of the XL70, the points are located in a case on the left-side of the camshaft. The timing advance mechanism is fitted behind the points.

2. On the XL70, the points are fitted to the magneto stator plate beneath the rotor.

REPLACEMENT

If replacement of the points is necessary, this is easily accomplished on all except the XL70 by disconnecting the primary wire, removing the two point securing screws and taking off the points. Install the new points after thoroughly cleaning off the contact surfaces with a non-oily solvent, and adjust the gap.

On the XL70, remove the left crankcase cover. Use the special puller to remove the magneto rotor after removing the rotor nut. Disconnect the primary wire, remove the points securing screw. Install the new point set and reset the gap. Check the ignition timing.

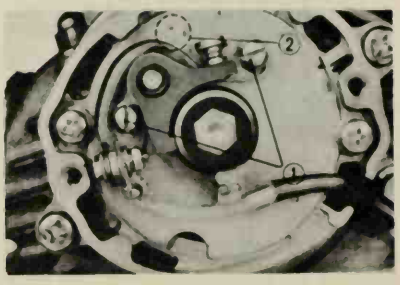


CAUTION: *Ensure that all insulating washers are correctly installed.*

GAPPING

Points should be filed (if necessary) and cleaned before gapping.

1. Remove the points cover. On the XL70, remove the magneto rotor cover.



2. Turn the engine over slowly until the points are open to their maximum gap. On the XL70, do this by observing the points through the cutout in the rotor. Other models may have a small indicator mark on the breaker cam which should be lined up with the heel of the points.

Point securing screw (3) is loosened slightly to change the point gap on the XL70

3. With the proper feeler gauge blade, check the gap. Proper gap for all models is 0.012–0.016 in. (0.3–0.4 mm).

4. If adjustment is necessary, loosen the two breaker securing screws (one on the XL70), and use a thin screwdriver at the pry slot provided to bring the gap to within the proper specification.

To adjust the point gap, loosen the two securing screws (1) and change the gap with a small screwdriver applied to the pry point (2)

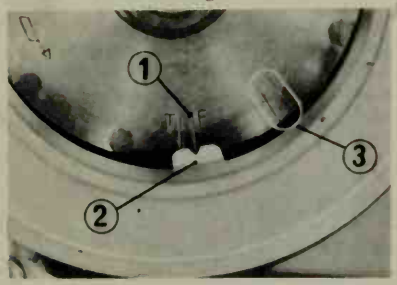
5. Tighten the screw(s) and recheck the gap. It may change slightly when the screws are tightened.

6. If it is not possible to correctly gap the points, the fiber heel is evidently worn, and the point set should be replaced.

NOTE: *The ignition timing on the XL70 is adjusted by changing the gap; therefore ignition timing should be checked whenever the points are gapped.*

Ignition Timing

ALL MODELS EXCEPT XL70



Static Timing

1. Remove the alternator rotor cover and the points cover. Remove the spark plug and the intake valve cover.

2. Hook the tester up. Remember that if a light is used on magneto-ignition machines, the primary wire should be disconnected.

3. Turn the engine over so that the engine is just beginning its compression stroke (the intake valve will go down and come up). Turn the rotor slowly in the normal direction of rotation (coun-

terclockwise). At the instant in which the "F" mark on the rotor aligns with the mark on the crankcase cover, the points should begin to open as indicated by the reaction of the test light or the meter.

The "F" (1) mark is the piston firing point with the timing not advanced. The slash marks (3) indicate full advance firing point. (2) is the stationary timing mark

4. If the points open before the marks align, the timing is too advanced. If they open after the "F" mark passes the stationary mark, the timing is too retarded.

5. If the timing is not correct, loosen the two phillips screws which secure the breaker point plate to the engine. Loosen them just enough to allow the plate to be rotated.

6. Turn the plate using a thin screwdriver applied to the pry slot provided so that the points open just as the "F" mark lines up with the stationary mark. If the timing was too advanced, turn the plate counterclockwise. If too retarded, rotate the plate clockwise.

7. Tighten the breaker plate screws and recheck the timing. Sometimes this will cause the plate to move slightly and throw the timing off.

Dynamic Timing

1. If a stroboscopic timing light is available, install the spark plug and hook up the light. The "F" mark on the rotor should line up the stationary mark at idle. Increase the engine rpm to about 4,000 rpm. At this point the two full advance timing marks should align with the stationary timing mark. Move the breaker plate as required so that the marks line up. Moving the plate clockwise will advance the timing and vice-versa.

Rotor "F" mark aligned with stationary timing mark (1)

NOTE: *A white grease pencil or some paint can be used on the rotor and crankcase cover timing marks to increase their visibility under the strobe light.*

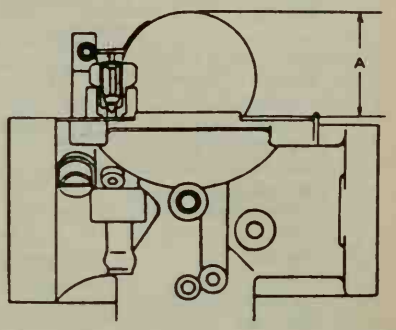
2. If full advance timing cannot be correctly set, check the operation of the timing advance mechanism behind the breaker plate. If the breaker cam is turned counterclockwise by hand and then released, it should return immediately to the unadvanced position. If it does not, check for weak or broken springs on the advance mechanism or for stuck timing weights.

XL70

The timing on this model is accomplished by changing the point gap.

1. Remove the spark plug and the magneto rotor cover.
2. Clean and gap the points to the proper specification as outlined under "Gapping."
3. Hookup the ohmmeter to ground and to the black wire coming from the points.
4. Turn the rotor slowly in the normal direction of rotation (counterclockwise). When the "F" mark on the rotor and the stationary timing mark on the crankcase align, the meter should indicate that the points have just begun to open.
5. If the points open after the "F" mark passes the stationary mark, the timing is too retarded; if they open before the "F" mark aligns, the timing is too advanced.
6. As noted above, ignition timing is corrected by changing the point gap. If the timing was retarded, increase the point gap. If it was advanced, decrease the point gap.

NOTE: *It should be possible to set the timing perfectly while maintaining the point gap within the specification given (0.012-0.016 in./0.3-0.4 mm). If the timing marks will not align when the point gap is within this specification, the points must be replaced. Wear of the fiber heel is one cause of this condition.*



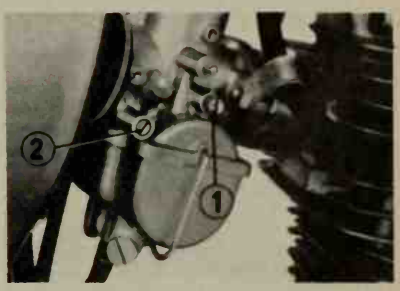
7. Check the timing with a stroboscopic timing light if one is available. At idle, the light should reveal that the "F" mark is lined up with the timing mark as above. At 4,000 rpm (full advance) the two advance marks should align with the timing mark. Adjust, if necessary, by increasing or decreasing the point gap as outlined in Steps 5 and 6.

Carburetor

ADJUSTING FLOAT LEVEL

Generally, float level will not need adjustment unless the carburetor has been disassembled, fuel delivery problems have been noted, or considerable mileage has been covered.

1. Remove the carburetor from the motorcycle.
2. Remove the float bowl. Remove the float bowl gasket.
3. Float level is defined as the measured distance from the float bowl mating surface on the carburetor body (gasket removed) to the top of the floats, when the tang of the float arm is just touching the end of the float needle. A special gauge is available to check the float level although a vernier caliper can also be used.



Float level is the distance "A" from the float bowl gasket surface (gasket removed) to the top of the floats

4. With the carburetor upside down, gradually lower the floats until the tang of the float arm just touches the end of the float needle. The tang should not depress the needle, but just contact it. Measure the distance from the carburetor body to the top of the floats. Compare the reading with the proper float level for your machine as given in the "Tune-Up Specifications" chart at the end of this section.
5. If adjustment is necessary, bend the float arm tang *only* to raise or lower the float level.
6. Float level will not be correct if the needle is worn, or if there is foreign matter on the needle seat.

IDLE SPEED AND MIXTURE

NOTE: *These items must be adjusted when the engine is at operating temperature.*

1. Ensure that the throttle cable adjustment is approximately correct so that the cable has enough slack to allow the throttle slide to be fully closed.
2. Screw the pilot screw in (carefully) until it bottoms lightly, then turn it out the number of turns shown in the "Tune-Up Specifications" chart at the end of this section.

Throttle stop (1) and pilot air (2) screws (all except 350/250)

3. Start the engine. When operating temperature is reached, adjust the throttle stop screw so that the engine idles as slowly as possible. Then turn the pilot screw in or out until the engine runs smoothly. It should not be necessary to vary the pilot screw more than one half turn in either direction from the given

4. Adjust the throttle stop screw so that the engine idles at the desired rpm.

NOTE: *If proper idling cannot be obtained using this method, it may be that the fuel system is clogged with dirt (check petcock, filter, carburetor), the plug is bad or too cold, the valves are improperly adjusted, or there is an air leak somewhere in the system.*

5. After adjusting the idle speed and mixture, adjust the throttle cable(s).

Engine and Transmission

NOTE: *For engine component inspection procedures, refer to "Engine Rebuilding" under the General Information section.*

ENGINE REMOVAL AND INSTALLATION

The following notes apply to all models:

1. Drain the oil before removing the engine.

2. Degreasing and thoroughly cleaning the engine before removal is highly recommended. Be especially attentive to the cylinder base and the underside of the crankcase, and around mating surfaces.

3. When disconnecting the final drive chain (except for endless chains), use a pliers to remove the masterlink spring clip. Do not pry the clip off with a screwdriver or it will be distorted and then must be replaced.

After disconnecting the chain, install the masterlink on one end of the chain to prevent loss. "Endless" chains have a riveted masterlink, and the chain must be removed with a special tool.

4. Upon installation, install the spring clip with the closed end facing the direction of chain rotation.

XL350/250

Top end service (removal of the head, piston, and cylinder) can be accomplished without removing the engine from the frame (see the appropriate section below), except for the XL250K models.

1. Disconnect the clutch cable at the engine. Remove the exhaust pipe, taking note of the exhaust pipe gasket at the cylinder which should be replaced rather than reused.

2. Remove the countershaft sprocket cover. Use an impact driver to loosen the cover screws.

3. Disconnect the final drive chain (if possible) and remove it from the countershaft sprocket.

If an endless-type drive chain is fitted, either use the special tool to break the chain or move the rear wheel forward to increase chain slack, remove the countershaft sprocket bolts and pull the sprocket off the countershaft, if possible.

4. Unbolt the carburetor manifold from the cylinder head. Note the O-ring behind the manifold. Replace it upon installation of the engine if it is not in perfect condition.

5. Remove the phillips head screw which secures the tachometer cable to the crankcase and pull out the cable.

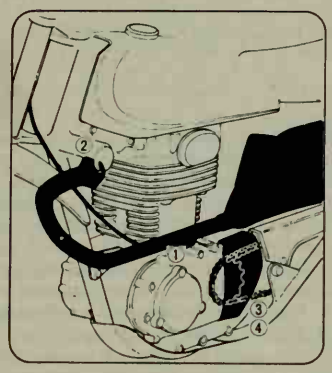
6. Remove the spark plug cap and loosen or remove the spark plug.

7. Disconnect the wires coming from the engine at the connector.

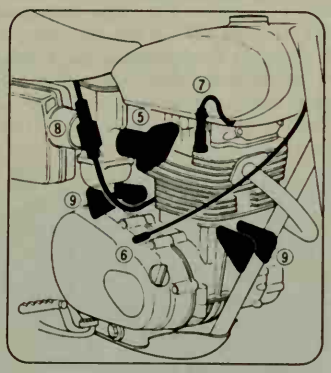
8. Remove the four engine mounting plates, and their nuts, bolts, and washers. Remove the engine from the frame.

9. Installation is the reverse of the above. Tighten the engine mounting bolts to 22–30 ft lbs.

10. When fitting the countershaft sprocket cover, coat the threads of the cover screws with lubricant or anti-seize compound to facilitate future removal. Secure the screws with an impact driver.

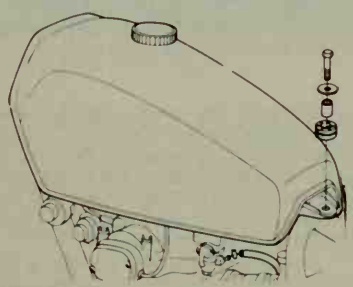


11. Use new gaskets at the exhaust pipe and intake manifold if necessary. Readjust the clutch cable.



XL175

The cylinder head, cylinder, and piston can be removed without taking the engine out of the frame. Refer to the appropriate section below.



1. Disconnect the fuel line at the petcock. Remove the rear mounting bolt and remove the gas tank from the motorcycle. Be sure that the rubber bushing, sleeve, and washer are not misplaced.

2. Remove the left rear (countershaft sprocket) cover. Disconnect the drive

XL350/250: remove the shaded components to remove the engine from the frame

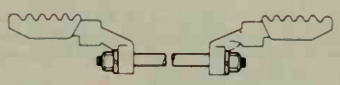
chain and disengage it from the sprocket.

3. Disconnect the clutch cable from the clutch mechanism in the left front crankcase cover and disconnect the cable from the engine.

4. Remove the screw which secures the tachometer cable to the cylinder head and pull out the cable.

5. Disconnect the breaker points wire and the plug near the upper frame tube, and the electrical wires coming from the engine at the plastic connector.

6. Disconnect the lead from the spark plug. Loosen or remove the plug. Unscrew the carburetor cap and pull out the slide assembly. Tie the slide out of the way to avoid damage when the engine is removed.



7. Loosen the screw securing the air cleaner hose to the carb.

8. Remove the muffler, unbolting it from the frame and cylinder head. The pipe gasket at the head should be replaced upon installation.

9. Remove the head stay nuts, bolts, and washers, and the plates.

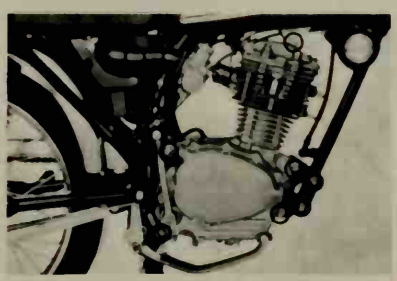
10. Remove the front engine mounting plates and their fasteners. Remove the footpeg securing nuts and the stud. Remove the engine from the frame.

11. Installation is the reverse of removal. Torque the mounting nuts and bolts to 22–29 ft lbs. When securing the footpeg mounting nuts, note that the nuts should each be equal distances onto the stud (i.e., approximately the same number of threads protruding from each nut).

When refitting the footpegs, tighten the nuts so that approximately the same number of stud threads show through on each side

12. Use a new exhaust pipe gasket if necessary. When fitting the sprocket cover, coat the threads of the screws with lubricant or an anti-seize compound to facilitate future removal. Tighten the screws with an impact driver. Adjust the clutch cable.

XL125/100



It is necessary to remove the engine from the frame to remove the cylinder head, cylinder and piston.

1. Remove the seat. Disconnect the fuel line at the petcock and remove the gas tank.

2. Remove the frame sidecovers. Disconnect the breaker points wires at the plugs near the ignition coil, and the electrical wires at the plastic connector near the battery.

3. Remove the gearshift lever (XL100) by loosening the pinch-bolt and pulling the lever carefully off the splined shaft.

4. Remove the countershaft sprocket cover. Loosen the cover screws with an impact driver to avoid damage.

Engine mounting bolts (XL100)

5. Disconnect the final drive chain.

6. Disconnect the spark plug lead. Loosen or remove the spark plug.

7. Unscrew the carburetor cap and pull out the slide assembly. Fasten it to the frame out of the way.

8. Move the spring which holds the air cleaner hose to the carburetor.

9. Disconnect the clutch cable at the engine. On the XL125, loosen the screw securing the tachometer cable at the engine and pull out the cable.

10. Remove the exhaust pipe.

11. Remove the engine mounting bolts and plates at the cylinder head and the front and rear of the crankcase and remove the engine from the frame.

12. Installation is the reverse of the above. Tighten engine mounting nuts to 15–22 ft lbs.

13. When fitting the countershaft sprocket cover, coat the screws with a lubricant or anti-seize compound to facilitate future removal. Tighten these screws with an impact driver.

14. Check the condition of the exhaust pipe gasket and replace it if necessary. Readjust the clutch cable.

XL70

The cylinder head, cylinder, and piston can be removed without removing the engine from the frame. Refer to the appropriate sections below.

1. Remove the seat by loosening the shock absorber capnuts and pulling it off. Disconnect the fuel line at the petcock and fold back the rubber mounting at the rear of the gas tank. Pull the gas tank back and off the machine.

2. Remove the frame sidecovers. Disconnect and remove the battery. Remove the tool box. Remove the chain guard. Remove the gearshift lever and the kickstarter lever.

3. Remove the engine left-side cover. Use an impact driver to loosen the phillips screws to avoid damage.

4. Disconnect the drive chain.

5. Remove the exhaust system after unbolting the muffler from the frame and the exhaust pipe from the cylinder head.

6. Loosen the carburetor air cleaner hose clamp screw, remove the air cleaner case mounting bolts, and remove the case.

7. Unscrew the carburetor cap and pull out the slide assembly. Tape the slide out of the way to avoid damage. Remove the manifold bolts at the cylinder and take away the manifold and carburetor as a unit. Plug the cylinder intake port with a clean piece of rag to keep foreign matter out.

8. Disconnect the electrical wiring at the plastic coupler. Remove the spark plug cap. Loosen the plug.

9. Disconnect the clutch cable at the engine.

10. Remove the two engine mounting plate bolts on the right engine mounting plate. Remove the long engine mounting bolts (two). The lower bolt is removed by loosening it from the left-side. Remove the right-side engine mounting plate.

11. Protect the frame tubes with a covering of some sort. Remove the engine by moving it forward in the frame, then swing the back of the engine out to the right and take the engine out of the frame.

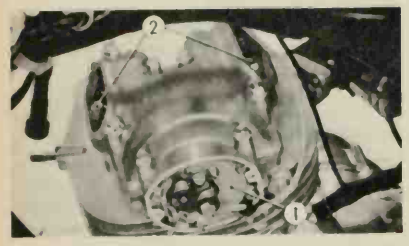
12. Installation is the reverse of the above. Tighten engine mounting bolts to 15–22 ft lbs. When installing the engine sidecover, coat the threads of the screws with a lubricant or anti-seize compound to facilitate future removal.

13. When installing the muffler, check the gasket for damage and replace it if necessary. Tighten the muffler bolt and the cylinder mounting nuts gradually.

Top End

REMOVAL

XL350/250



1. The top end assembly can be removed with the engine in the frame after removing the gas tank except for XL250K models. Remove the exhaust pipe and carburetor and manifold. Remove the spark plug.

2. Remove the breaker points cover and the valve adjustment caps. Mark the position of the breaker plate relative to the cam cover with a scribed line to preserve ignition timing. Remove the breaker plate securing screws and take off the plate. Remove the magneto rotor cover.

3. Remove the bolt from the breaker point end of the camshaft and remove the breaker cam and the timing advance mechanism.

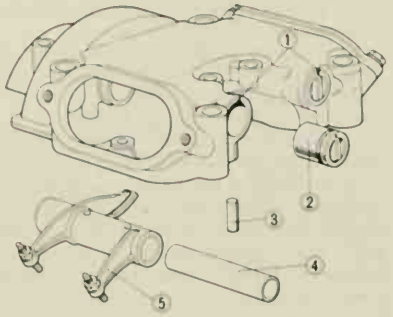
4. Place the piston at TDC on the compression stroke so that all valves are closed.

5. Remove the two cam cover bolts (6 mm) which are just inside the valve adjustment caps.

Remove the breaker mounting plate (1), two of the cam cover bolts are accessible after the valve adjustment caps are removed

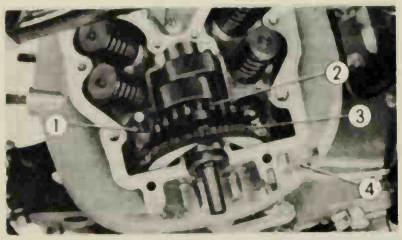
6. Remove the eight remaining cam cover bolts. Tap lightly with a plastic mallet if necessary to break it free from the head, and remove the cam cover. The rocker arms and shafts will remain in the cam cover.

Note the three dowel pins in the cam cover. Two secure the rocker arm shaft plugs. The other is an oil bushing.



7. Rocker arms, shafts, and plugs should be marked as they are removed so that they can be installed in their original locations. With pliers, pull out the two dowel pins in the cover which secure the rocker arm shaft plugs. Pull out the plugs.

8. Remove the rocker arm shafts and the rocker arms.



9. Loosen the cam chain tension adjuster bolt. Remove the tensioner mounting bolt at the left rear of the cylinder head. Remove the oil seal from the camshaft.

10. Stuff a clean rag into the head all around the cam sprocket. Carefully remove the sprocket bolts. It may be necessary to hold the crankshaft in place with a wrench on the magneto rotor bolt while removing the sprocket bolts.

11. Lift the cam chain up off the sprocket to the right-side of the sprocket. Loop a length of wire around the chain and secure it to a fixed point so that the chain doesn't fall into the cylinder when the head is removed.

The rocker arm shaft plugs (2) should have their marks lined up with the cam cover marks (1) when they are installed. Fit the dowel pins (3) to secure the plugs (XL350/250)

To remove the head, remove the plug (1) and the nut beneath it, the other cylinder head nuts, disengage the cam chain (2) from the sprocket (3) and remove the chain tensioner mounting bolt (4) (XL350/250)

12. Remove the cam. Remove the cam sprocket.

13. Remove the sealing cap in the cylinder head, if fitted. There is a cylinder head nut beneath the cap. Remove the cylinder head securing nuts on the top of the head, and the four nuts beneath the head in the cylinder fins.

14. Carefully lift up the head then remove it from the machine. If the head is stuck it may be removed by striking carefully with a plastic mallet at the sides of the head. Remove the head gasket.

15. To remove the cylinder, first be certain that the area around the cylinder base is clean. Remove the three nuts at the bottom of the cylinder on the left-side.

16. Lift the cylinder up until a clean rag can be stuffed beneath it into the crankcase. This will catch any dirt or pieces of broken piston ring which might otherwise fall into the crankcase when the cylinder is removed.

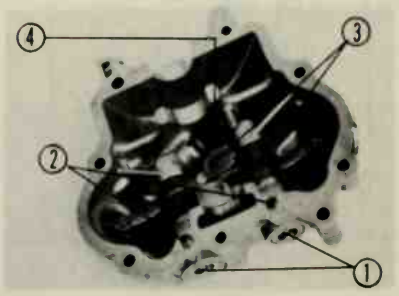
17. Remove the cylinder from the studs, catching the piston as it comes out of the bore.

18. Before removing the piston, mark the exhaust side on the skirt so that there will be no problem installing it correctly. The piston crown also has marks provided by the factory. Remove the piston wrist pin circlips with needlenose pliers. Use new ones on assembly.

19. With a suitable sized drift, push out the wrist pin while supporting the piston with your other hand.

CAUTION: *Use steady pressure only. Do not strike the pin. If it resists, the piston crown may be heated gently and evenly with a propane torch until the pin can be removed.*

20. Remove the cylinder base gasket.



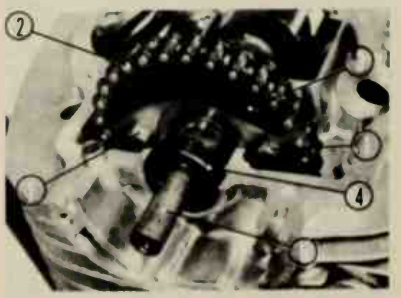
XL175

1. The top end can be removed with the engine in the frame. Remove the gas tank, exhaust system, and carburetor.

2. Remove the top engine mounting brackets. Disconnect the tach cable from the head. Remove the ignition coil. Remove the breaker point cover and gasket. Remove the valve adjustment covers.

3. Mark the position of the breaker point plate relative to the cam cover to preserve ignition timing upon reassembly. Remove the plate securing screws and take off the breaker plate.

4. Remove the bolt from the breaker point end of the camshaft and pull out the breaker cam and timing advance assembly.



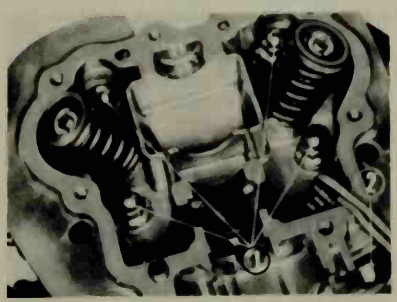
Rocker arms (3), shaft plugs (1), plug securing dowel pins (2), and tach drive (4) (XL175)

5. Remove the spark plug. Remove the alternator cover. Turn the engine over so that the "T" mark on the rotor is aligned with the mark on the crankcase. The piston is now at TDC. Check that the valves are closed. If not, rotate the engine 360° and align the "T" mark.

6. Remove the eight bolts which secure the cam cover to the head. Remove the cover. If stuck, the cover may be freed by tapping gently with a plastic mallet.

7. Rocker arms, shafts, and shaft plugs should be marked for position as they are removed so that they can be installed in their original locations. With pliers, pull out the dowel pins in the cam cover which secure the rocker arm shaft plugs. Pull out the plugs; remove the shafts.

Cam chain sprocket bolts (1), chain (2), sprocket (3), oil seal (4), and camshaft (5) (XL175)



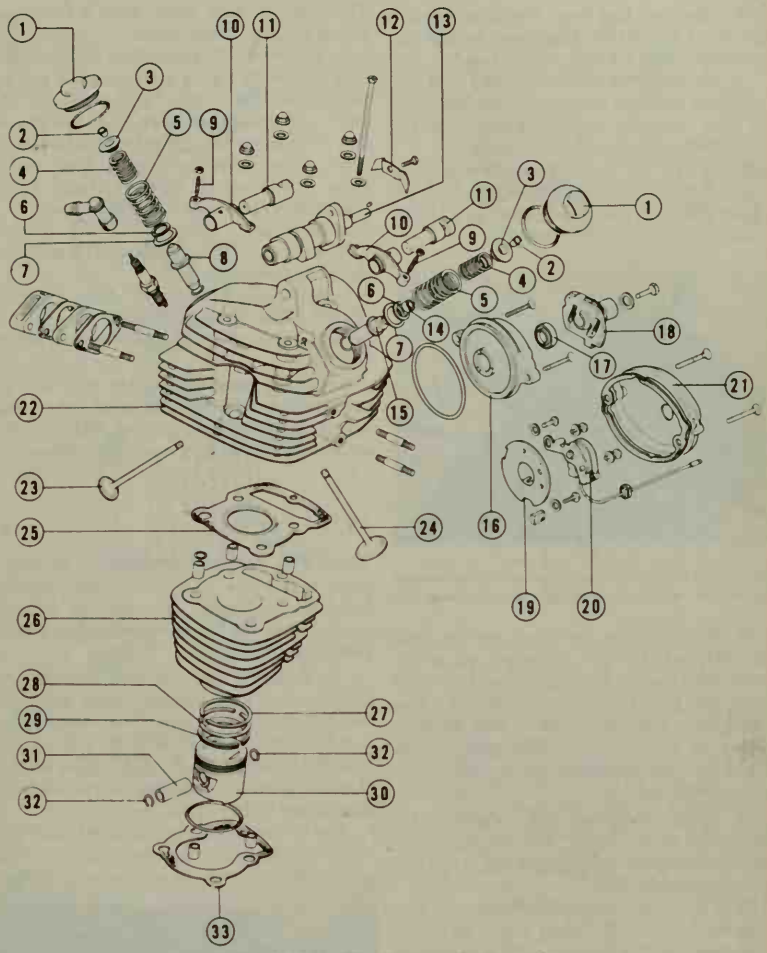
8. Although not usually necessary, the tachometer gear assembly can be removed from the cam cover after removing the snap-ring from the gear shaft.

9. Carefully remove the two cam sprocket bolts, taking care to ensure that the bolts do not drop into the crankcase. Remove the camshaft oil seal. Loosen the cam chain adjuster bolt and remove the chain tensioner mounting bolt from the top left-side of the cylinder head.

10. Loop a length of wire around the cam chain attaching it to a fixed point so that the chain will not fall into the crankcase when the cam is removed.

11. Remove the camshaft, holding the sprocket as the cam is removed. Then remove the sprocket.

12. Loosen each of the four cylinder head capnuts and bolt ¼ turn at a time until loose, then remove them. Remove the cylinder head. If stuck, it may be freed by striking the side of the head with a plastic mallet. Remove the head gasket.



Cylinder head nuts (1) and cam chain tensioner mounting bolt (2) (XL175)

13. Remove the two cylinder bolts at the cylinder base. Lift up the cylinder and stuff a clean rag between the cylinder and the crankcase as soon as the cylinder clears the case. This will catch any dirt or pieces of piston ring which might otherwise fall into the crankcase when the piston is removed. Continue lifting the cylinder up and off the studs. Catch the piston as it comes out of the bore so that it doesn't strike the studs.

14. To remove the piston, remove the wrist pin circlips with needlenose pliers. Push out the wrist pin with a suitable drift, while supporting the piston with the hand.

CAUTION: *Never strike the wrist pin to remove it. Use steady pressure only. If the pin resists removal, gently heat the piston crown with low heat until the pin can be pushed out.*

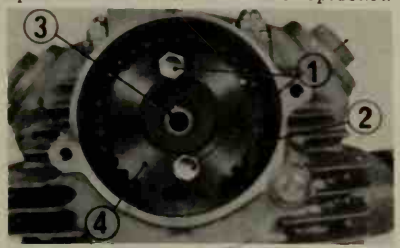
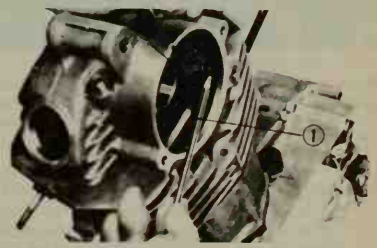
XL125/100 (1975 and Earlier)

1. Remove the engine from the frame.



2. Remove the breaker point cover. Scribe a line across the breaker plate to the engine to preserve ignition timing. Remove the two breaker plate screws and remove the plate. Remove the valve adjusting hole caps and loosen the adjusters.

3. Remove the bolt which secures the breaker cam. Pull the breaker cam and spark advance assembly off the camshaft.

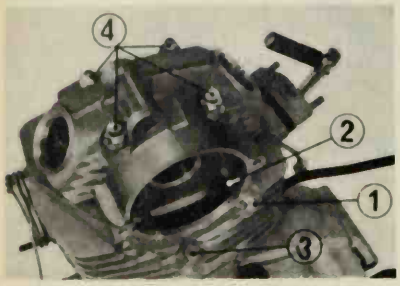


4. Remove the two screws which hold the breaker point housing to the engine. Use an impact driver to loosen these screws. Remove the housing.

5. Loosen the cam chain adjuster screw locknut (on the crankcase) and unscrew the tensioner screw a few turns. Place a clean rag beneath the cam sprocket, and carefully remove the sprocket bolts. Remove the sprocket. Loop a piece of wire around the cam chain and secure it to any fixed point to prevent the chain from falling into the crankcase.

6. Pull out the camshaft. Note that the camshaft will have to be turned to allow the intake and exhaust lobes to clear the opening through which the cam is removed. Perform this operation carefully. Hold the chain out of the way as the cam is removed.

Sprocket bolts (1), cam chain (2), camshaft (3), and sprocket (4)

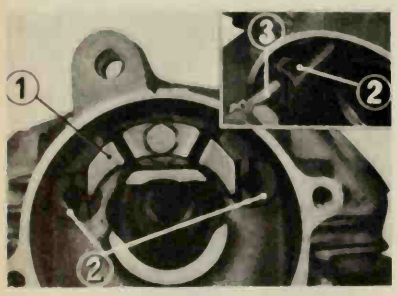


Prying the tensioner (2) out of its seat with a screwdriver (1)

7. Remove the cam chain tensioner mounting bolt in the head and detach the tensioner from its seat in the head.

8. Remove the cylinder head bolt beneath the breaker point housing. Remove the four capnuts on top of the cylinder head. Remove the cylinder head.

NOTE: *If the head resists removal, is may be freed by tapping with care at the sides of the head with a plastic mallet.*



Cam chain tensioner mounting bolt (1), tensioner (2), cylinder head bolt (3), cylinder head capnuts (4)

9. Remove the cam chain guide from the cylinder. Lift the cylinder up on its studs until there is enough room to stuff a clean rag between the cylinder and the crankcase. This will catch any foreign matter or pieces of broken ring which might fall into the cases when the cylinder is removed.

10. After removing the cylinder, remove the piston wrist pin circlips with needlenose pliers. Push out the wrist pin with a suitable drift.

NOTE: *The wrist pin should be pushed out with steady pressure while supporting the piston with one hand.*

11. To remove the rocker arms from the cylinder head, first remove the rocker arm shaft retaining plate. Thread a 6 mm bolt into the rocker arm shafts and pull them out of the head (the cylinder head bolt is 6 mm and can be used for this operation). Mark each rocker arm and shaft for position and keep the pairs together so that each rocker arm can be installed on its proper shaft.

Remove the bolt which secures the rocker arm shaft retaining plate (1), and pull out the rocker arm shaft (2) with a puller bolt (3) 6 mm thread diameter

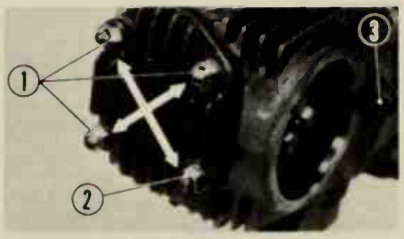
XL125/100 (1976)

1. The cylinder head on 1976 models has been modified to a two-piece type instead of the earlier one-piece casting. The head is now fitted with a cover secured by four allen bolts.

2. Removal, disassembly, and installation of the top end components is performed in the same manner as for the 1975 and earlier engines. It is not necessary to remove the cylinder head cover in order to remove the camshaft or rocker arms. Its removal, however, may facilitate removal of valves and inspection of cam bearings.

3. Refer to "XL125/100 (1975 and Earlier)" for procedures.

Specifications for the 125cc engine (1976) have been changed. Be sure to refer to the correct chart at the end of this section.



4. When assembling, be sure the oil seal rubber near the right-side cam bearing is in place. Use gasket sealer on the cylinder head cover mating surface.

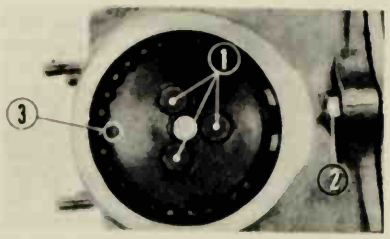
XL70

1. The engine need not be removed from the frame to remove the cylinder head and cylinder. Remove the exhaust system and the carburetor and manifold from the cylinder.

2. Remove the magneto or alternator rotor cover. Remove the spark plug and the valve adjuster caps. Turn the engine over until the intake valve goes down and comes up, and turn it a bit farther so that the "T" mark on the rotor aligns with the stationary index mark.

The piston is now at top dead center on the compression stroke (both valves closed).

Remove the three capnuts (1), and the hex nut (2) to remove the cylinder head cover. Remove the cylinder head bolt (3) before attempting to remove the head (XL70)



3. Loosen each cylinder head cover nut ¼ of a turn at a time until they are loose, then remove them. Note the copper washer beneath the hex nut. This is an oil sealing washer and must be refitted in the proper location, or replaced if damaged.

Tap the cover lightly with a soft-faced or plastic mallet to free it if stuck.

4. Remove the bolt from the right-side of the cylinder head. This will enable the left-side cylinder head cover to be removed.

5. Remove the two screws on the right-side cylinder head cover and remove the cover.

6. Turn the engine over (if necessary) so that the piston is at top dead center (the "0" mark on the camshaft sprocket will be toward the top of the head).

Align the sprocket mark (3) with the top of the head before removing the sprocket bolts (1) (XL70)

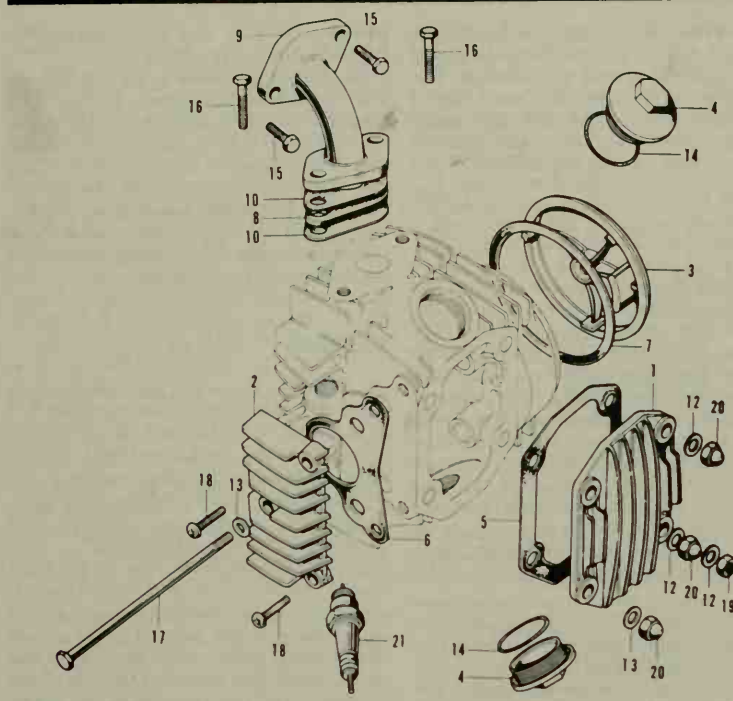
7. Remove the three sprocket mounting bolts, and push in on the camshaft to disengage it from the sprocket. Remove the sprocket after disengaging it from the cam chain.

NOTE: *It may be necessary to hold the camshaft in position while removing the sprocket bolts and this can be done if the engine is in the frame by engaging the transmission. If the engine is not in the frame, secure the magneto rotor or the countershaft sprocket.*

8. Remove the cylinder head mounting bolt on the left-side of the head. Remove the head, tapping around the mounting surface with a plastic mallet if it is stuck.

9. When the head is removed, remove the two locating pins at the head mating surface and ensure that they are in place when the head is refitted. To remove the rocker arms, thread a 6 mm bolt into the right-side of the rocker arm shafts and pull them out. Keep each rocker arm shaft with its own rocker arm for proper installation. Push the camshaft out of the head.

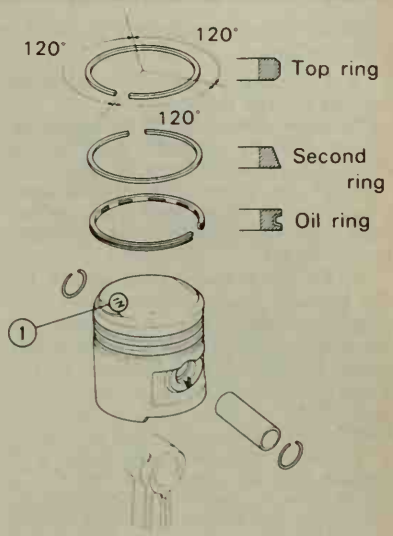
Removing the rocker arm shaft with a 6mm puller bolt (XL70)



NOTE: *The cylinder head or cylinder mounting bolt can be used to remove the rocker arm shafts.*

10. Unscrew and remove the cam chain guide roller pin from the left-side of the cylinder and remove the guide roller.

11. Remove the cylinder mounting bolt on the left-side and pull off the cylinder. Do not allow the piston to strike the studs as it comes out of the cylinder. Check the location of the two hollow dowel pins on the cylinder studs. Remove these and make sure that they are installed when assembling the top end.



12. To remove the piston, remove the wrist pin circlips with needlenose pliers and push out the wrist pin.

NOTE: *Use steady pressure while removing the wrist pin. Support the piston with your other hand. Do not strike or attempt to force out the pin.*

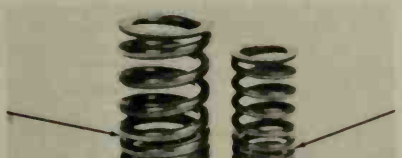
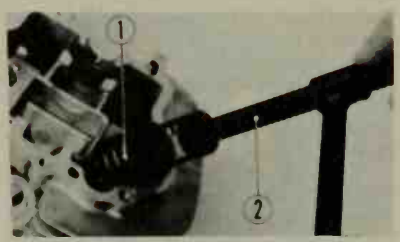
Cylinder head assembly (XL70)



Ring end-gaps should be spaced 120° apart. The piston marking shown must be installed toward the intake side of the head. Note the difference between the top and bottom compression rings

On models with two-rail oil rings, place the oil rail end-gaps to either side of the expander ends as shown. 1, 2, and 3 are the compression and oil ring cross-sections, 4 is the expander, 5 is the piston ring mark

TOP END SERVICE



1. Before removing the valves, note that most models use progressively wound valve springs and that these types of springs are always installed with the close pitch side toward the head. Also, each spring should be assembled to its own valve, and each valve to its guide. Mark the pieces for location as they are removed.

Note that the close coil of the progressively wound valve springs are installed toward the head

2. Valves can be removed after compressing the valve springs with a spring compressor. On some machines, they can be removed with a suitably sized socket. Turning the head upside down and pressing the valve spring against the socket while holding the valve against its seat should allow the valve keepers to fall out. When they do so, the spring assembly and valve can be removed. Remove the retainer, springs, spring seats and any washers fitted. Remove the valve guide oil seal.

NOTE: *New valve guide oil seals should be used.*

Removing the valve spring (1) with a valve spring compressor (2)

3. Before installing the rings on the piston, first note that the two compression rings are not interchangeable. The wedge-shaped ring is the lower compression ring.

Also note that rings must always be installed so that the manufacturer's mark (the small letter near the end-gap) faces *up* when the rings are in place.

4. If two-rail oil rings are used, install one rail on the piston below the oil ring groove. Install the oil rail expander in the groove, then move the lower rail into the groove. Install the upper oil rail.

5. Arrange the ring end-gaps 120° apart, but do not position any end-gap at the very front or the very back of the piston (perpendicular to the wrist pin), or directly above the wrist pin holes.

If a two-rail oil ring is used, position the end-gap of the oil ring expander 120° from the lower compression ring, then position the end-gaps of the oil rails about 45° (20–30 mm) on either side of the expander end-gap.

INSTALLATION

XL350/250

1. Install the cylinder base gasket.

2. Install one wrist pin circlip and place the piston on the connecting rod. Be certain that the arrow stamped onto the crown points toward the exhaust port, or that the "IN" on the crown is on the intake side. Install the wrist pin and the other circlip.

NOTE: *Use new circlips. Be sure that the circlips are properly seated in the grooves with the end-gaps upward.*

3. Position the piston ring end-gaps 120° apart. If the oil ring is the two-rail type, position the top rail end-gap 20–30 mm from the gap of the expander, and the lower rail gap 20–30 mm from the expander gap in the opposite direction.

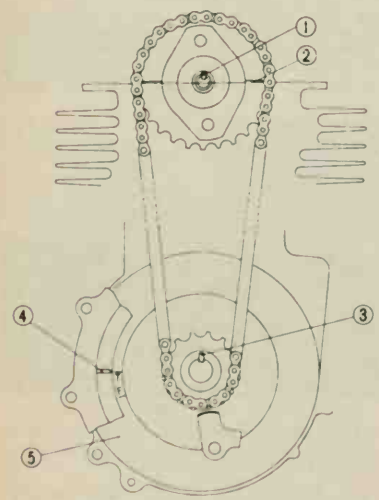
No ring end-gap should be 90° from the

wrist pin plane, or directly above the wrist pin holes.

4. Lubricate piston skirt and rings thoroughly with motor oil.

5. Install the cylinder, having an assistant carefully compress each ring as the piston enters the bore.

6. Fit the three cylinder base nuts. These should be torqued to the proper value after the cylinder head nuts have been torqued.



7. Fit the cylinder head gasket. Fit the cylinder head. Cylinder head nuts should be tightened in a cross pattern in increments of a few ft lbs until the proper torque is reached on all the nuts. Do not forget to torque the cylinder base nuts as well. Refer to the "Torque Specifications" chart at the end of this section.

8. Install the camshaft, slipping it through the cam chain and sprocket in the reverse of the removal procedure. Grease the lips of a new camshaft oil seal and install it.

9. The cam must be lined up correctly for proper valve timing. Remove the rotor cover. Turn the engine over so that the "T" mark on the rotor is lined up with the crankcase mark. If the rotor has been removed, turn the crankshaft so that the rotor woodruff key slot is vertical. The piston is now at TDC. Arrange the camshaft sprocket so that the marks on the sprocket are aligned with the mating surface of the cylinder head. Position the camshaft so that the dowel pin faces upward. Install and tighten the sprocket bolts to 13–16 ft lbs.

10. Install the tensioner bolt. Assemble the cam cover. When fitting the rocker arm shaft plugs, line up the dot on each plug with the mark on the cover. Push the locating dowel pins into position.

11. Use a heat-resistant sealant on the cover mating surface. Do not overapply or some may run into the inside of the engine when the cover is secured.

To effect valve timing, align the alternator rotor "T" mark with the timing mark (4) or the woodruff key in a vertical position (3). Set the camshaft so that the pin is pointing upward (1) and the sprocket marks should align with the upper surface of the cylinder head

12. When fitting the spark advance mechanism, line up the slot in the mechanism with the pin on the camshaft. The remainder of the assembly procedure is straightforward. Adjust the cam chain tension, valve clearance, and ignition timing before starting the engine.

XL175

1. Install one wrist pin circlip and place the piston on the rod so that the mark on the crown is positioned on the exhaust side or the "IN" letters are located on the intake side. Install the wrist pin and the other circlip. Use *new* circlips and be sure that they are firmly seated in their grooves. The circlip end-gaps should point upward.

2. Arrange the piston ring end-gaps 120° apart. None of the end-gaps should be perpendicular to the wrist pin or directly above the wrist pin holes. Lubricate the piston skirt and rings with motor oil.

3. Fit a new cylinder base gasket. Install the cylinder after first ensuring that all cylinder guide pins and O-rings are in place. Compress the piston rings carefully as the cylinder is lowered so that they enter the bore without catching. Install the cylinder bolts.

4. Fit a new head gasket. Install the head, making sure that the head dowel pins are in place. Pull the cam chain through and seat the head on the cylinder.

5. Install and tighten the four cylinder head nuts and the bolt evenly and in a cross pattern. These should be tightened in increments of 2–3 ft lbs until the proper torque is attained. After torquing the head, check the torque of the cylinder bolts.

6. Install the camshaft sprocket, and insert the cam through it. It is necessary to align the sprocket to ensure proper valve timing. Rotate the crankshaft until the "T" mark on the alternator rotor aligns with the index mark on the case. If the rotor has been removed, turn the crank so that the woodruff key is facing upward.

7. Line up the marks on the cam sprocket with the upper mating surface of the cylinder head. Align the camshaft so that the timing advance pin on the cam is on top. Install the cam sprocket bolts, tightening them to the proper torque. These bolts should be secured with thread locking compound. The valve timing is now correct. Install and secure the chain tensioner mounting bolt.

8. Install a new camshaft oil seal, greasing the lips of the seal before installing it on the camshaft.

9. Install the tachometer gear assembly and the rocker arms in the cam cover. The rocker arm shaft plugs are marked, and the mark should be aligned with the corresponding mark on the cam cover. Position the plugs in this manner and push in the dowel pins. Install the cam cover after applying a heat-resistant sealing compound to the cover mating surface. Do not apply too much of the compound or it may run down inside the engine when compressed.

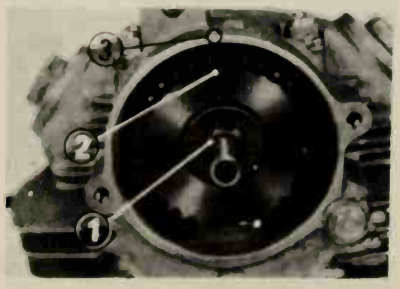
10. Install the cover bolts and tighten them evenly and in a cross pattern. The remainder of the assembly procedure is straightforward. When fitting the breaker cam assembly, note that the notch in the assembly must line up with the pin on the cam. Adjust the cam chain, ignition timing, and the valves, and recheck these adjustments after the engine has been run a few miles and cooled.

XL125/100

1. Install one wrist pin circlip and place the piston on the connecting rod so that the "IN" stamped on the piston crown is on the intake port side. Install the wrist pin and the other circlip.

Be sure to use new circlips. They must be properly seated in their grooves, with the end gap pointing downward.

Arrange the ring end-gaps so that they are 120° apart. No end-gap should be perpendicular to the wrist pin or directly above the wrist pin hole. If a two-rail oil ring is fitted, position the end-gap of the upper rail 20–30 mm from the ends of the expander, and the end-gap of the lower rail 20–30 mm in the opposite direction.



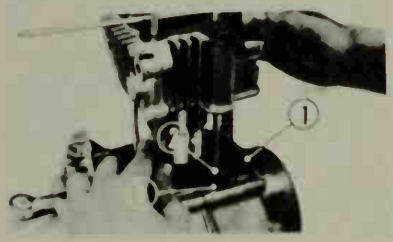
2. Fit the cylinder base gasket. Make sure that all O-rings and locating pins are installed in the cylinder, and lower the cylinder over the piston, compressing the rings with your fingers as the piston enters the bore. Pull the cam chain up through the cylinder. Install the cam chain guide.

3. Assemble the rocker arms in the head if removed. Fit a head gasket, and install the head. Pull the cam chain through and tie it aside. Fit the cam chain tensioner into its seat and install the tensioner mounting bolt.

4. Tighten the cylinder head capnuts and bolt in a cross pattern and in increments of 2–3 ft lbs until the proper torque of 13–14.5 ft lbs is reached.

5. Lubricate and install the camshaft. Arrange the cam so that the locating pin for the spark advance mechanism points upward.

6. Remove the alternator rotor cover and turn the crankshaft so that the "T" mark on the rotor is aligned with the mark on the stator. The piston is now at top dead center. Install the cam sprocket on the camshaft, looping the cam chain



The "0" mark on the cam sprocket (2) must align with the mark (3) on the head with the piston positioned at TDC

over it, so that the "0" mark on the sprocket is aligned with the mark on the top of the cylinder head. Be sure that the rotor "T" mark is still aligned. Fit the camshaft sprocket bolts and tighten them to 6–9 ft lbs. These bolts should be secured with thread locking compound. The valve timing is now adjusted.

7. The remainder of the procedure is the reverse of disassembly. Be sure to engage the slot in the timing advance mechanism with the pin in the camshaft. Adjust the cam chain, check ignition timing, etc. before starting the engine. Check cylinder head torque after the engine has been run and cooled off.

XL70

1. Install one wrist pin circlip and place the piston on the connecting rod. The triangular mark on the piston crown must be positioned on the *cam chain* side. Insert the wrist pin and the other circlip. Use new circlips and be sure that the end-gap points downward and that they are properly seated. Arrange the piston rings so that the end-gaps are 120° apart with no end-gap perpendicular to or directly above the wrist pin. Lubricate the wrist pin, rings, and piston skirt with motor oil.

Installing the cylinder. Be sure that the dowel pins (1 and 2) and the O-ring are in place

2. Be sure that the O-ring is in place in the crankcase oil passage and the hollow dowel pins are installed on the cam chain side studs. Fit a new cylinder base gasket. Install the cylinder, compressing the rings with your fingers as the piston enters the bore. Feed the cam chain through the cylinder as it is seated. Install and tighten the cylinder mounting bolt.

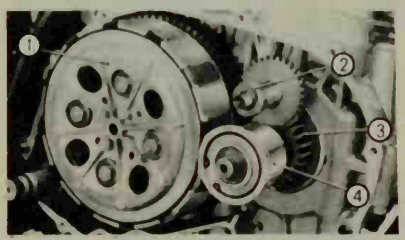
3. Install the cam chain guide roller and the roller pin.

Installing the head while supporting the cam sprocket; note dowel pin and O-ring (2 and 3) installed

4. Install the two hollow pins on the studs: one on the top right stud, the other on the left bottom. Fit the O-rings to the oil passage and to the stud oil passage; fit the head gasket.

5. Install the head, complete with rocker arms and cam, threading the cam chain with its sprocket through, and securing them with a length of wire or a screwdriver.

6. Turn the magneto rotor so that the "T" mark on the rotor is aligned with the index mark on the crankcase. Set the cam sprocket "0" mark at the top of the head. Install and tighten the sprocket bolts to 4–7 ft lbs. Thread locking compound should be used on these bolts. Lubricate the top end components.



7. The remainder of the procedure is the reverse of disassembly. Note that the cylinder head cover hex nut and its copper washer are installed on the lower left stud. Install the head mounting bolt. Tighten the head cover nuts in a cross pattern and in increments of 2–3 ft lbs until the proper torque of 6.5–8.7 ft lbs is reached. Adjust the cam chain and tappet clearance before starting the engine.

h. When fitting the cover, be sure that the dowel pins and the screws are correctly located. The screws are of different lengths.

LEFT CRANKCASE COVER COMPONENTS

The left crankcase cover contains the alternator or magneto and the countershaft sprocket, and the gearshift linkage on some models.

All components can be serviced with the engine in the frame.

Certain precautions should be observed when handling the electrical components:

a. The rotor must be removed with a special puller. Do not attempt to pry the rotor off the tapered crankshaft;

b. Do not heat or strike the rotor as this may affect its magnetic properties;

c. Do not drop the rotor once it is removed. Place it where it will not pick up stray bits of metal;

d. Be sure that the rotor is perfectly clean before installation. Push it on its shaft and tighten the rotor bolt or nut to seat it. Do not strike it;

e. Be sure that all electrical wiring is properly routed and seated in the rubber grommets provided before installing the crankcase covers. Be certain that the cover will not pinch the wires, or that the wiring will not touch any moving part;

f. Be sure that parts such as the rotor and countershaft sprocket bolts are tightened to the proper torque. Refer to the "Torque Specifications" chart at the end of the section.

XL350/250

The left crankcase cover is in two parts, the rearmost section being for the countershaft sprocket. The forward section of the cover can be left in place if only the sprocket needs inspection. The forward part of the cover includes the clutch lifter lever, the alternator, and the gearshift linkage.

Removal and Installation

1. To remove the forward section, drain the oil. Remove the left-side footpeg. Remove the gearshift lever. Disconnect the clutch cable at the engine. Disconnect the alternator wiring at the plastic connector and the neutral switch wire.

2. Remove the cover screws and remove the covers.

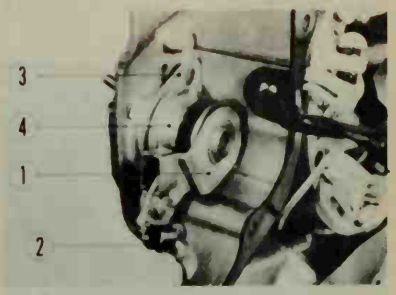
3. If the alternator rotor must be removed, take it off before removing the countershaft sprocket. Keep the crankshaft from turning and remove the rotor bolt. Use the special puller and remove the rotor. Remove the woodruff key.

4. Remove the two countershaft sprocket bolts and the lockplate. If the engine is in the frame, move the rear wheel as far forward as possible and pull the sprocket off its shaft.

5. To remove the shift linkage, unscrew and remove the shift drum stopper nut; remove the stopper and spring. Disengage the fingers of the shift arm from the shift drum pins and pull the gearshift shaft assembly from the case. Unscrew and remove the shift drum stopper shaft and the neutral stopper and spring.

6. To remove the clutch lifter lever from the side cover, unscrew and remove the clutch adjusting screw, pull out the clutch pushrod end piece. Remove the lockbolt and pull out the lifter lever.

7. Installation is the reverse of removal. Apply a bit of lubricant to the crankshaft taper to facilitate future removal of the rotor.



XL175

If service to the countershaft sprocket only is required, only the rearmost section of the left crankcase cover need be removed.

1. Remove the countershaft sprocket cover. Disconnect the chain. Remove the two sprocket bolts and the lockplate and pull off the sprocket.

2. To remove the forward section of the cover, drain the oil. Disconnect the alternator wiring at the plastic connector. Remove the left-side footpeg and the gearshift lever. Disconnect the clutch cable at the engine. Remove the clutch locking bolt, and the cam chain adjuster cap.

3. Use the special rotor puller to remove the rotor. Remove the woodruff key from the crankshaft.

4. To remove the countershaft sprocket, remove the two bolts and the locking plate, disconnect the chain and pull off the sprocket.

5. To remove the magneto coils, remove the two screws which secure the stator plate and rotate the plate slightly to remove it.

Magneto stator plate (1) securing screws (2)

Note that there are O-rings beneath the stator plate mounting screws, as well as an O-ring around the stator plate and an oil seal in the center. These components must be in good condition or replacement is necessary. The plate seal may be replaced by driving the old seal out and carefully pressing a new one straight in. Grease the lips of the seal before installation.

6. Assembly is the reverse of the above.

COMPONENT INSPECTION

NOTE: *Where necessary, refer to the specifications charts at the end of this section for wear limits and tolerances.*

The following procedures refer to all models.

Gearshift

Note those procedures applicable to the type of shift linkage fitted to your model.

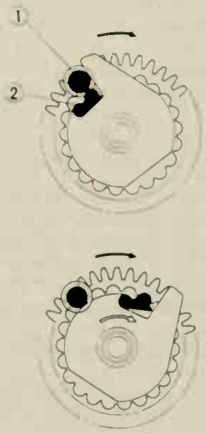
1. Check the splines on the gearshift shaft. If the splines are broken or torn to such an extent that it is difficult to properly secure the shift lever, replace the shaft.

2. Check the shift arm. Be sure that it is not bent. Check that the fingers of the shift arm are not bent or worn.

3. Check the condition of the springs in the shift linkage, especially the shift lever return spring. If any spring has lost its tension, or fails to hold its components properly, it must be replaced.

4. Check that the return spring pin (where fitted) is secure in the case.

Kick-starter



1. Check the splines on the kick-starter shaft and replace the shaft if they are damaged so that they will not secure the kick-starter lever properly.

2. If the kick-starter gear has a plain bore, check that it is not galled or worn. If the gear has a splined bore, check that the splines are in good condition, and that the gear does not have excessive backlash on its shaft.

3. Check the condition of the gear teeth. On models with the ratchet-type shifter, the teeth on the side of the kick-starter gear are critical. If chipped or worn, the gear should be replaced.

4. Check the condition of the teeth on the ratchet gear and replace the gear if they are worn.

5. On the XL350/250, check the condition of the inner teeth of the kick-starter gear. Check the kick-starter pawl as well

XL350/250 kick-starter operation

Both must be in very good condition. When the kick-starter assembly is installed, it should be possible to rotate the gear easily when the pawl of the spring retainer is resting against the stopper bolt. If the pawl is rotated clockwise, however, it should not be possible to turn the gear. If it is, either the gear pawl or the inner teeth of the gear are worn.

6. Check that the gear splines on the kick-starter shaft (where fitted) are in good condition. Check that the kick-starter shaft stopper or spring retainer and the stopper on the crankcase are not worn or chipped. If a stopper bolt is fitted, be sure that it is firmly secured in the case.

7. Check that the kick-starter shaft return spring is able to hold the kick-starter lever firmly in place. If the lever fails to return to its proper position, replace the return spring.

8. Check the retainer spring fitted to ratchet-type shifters, and replace it if bent or otherwise damaged.

Oil Pump

Test procedures can be found in the "Lubrication Systems" section. When installing the pump or related parts, new O-rings and gaskets should always be used.

Alternator

1. For electrical tests, refer to the "Electrical Systems" section.

2. Check the rotor and stator for signs of wear. If there has been contact between the rotor and the stator assembly, this condition must be rectified. In addition, the components should be tested to make sure that they still operate properly.

3. Check that the stator assembly is securely mounted, and properly aligned. If the rotor has contacted the stator, check for play in the crankshaft. This condition may sometimes be caused by a bad crank bearing or bent crankshaft.

4. Check that the rotor has little or no

run-out as it turns. If run-out exists, determine the cause.

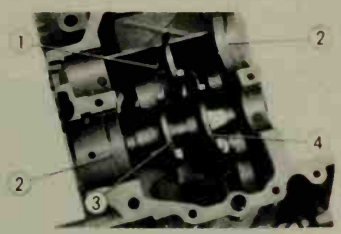
5. If scoring on either the rotor or the stator components is severe, the part(s) should be replaced.

Lower End and Transmission

The following sections deal with service to the crankshaft, gear clusters, and shift drum assembly, and the removal and replacement of items such as the kick-starter shaft on models where it is necessary to split the crankcases to gain access to them.

SPLITTING THE CRANKCASES

XL350/250/175

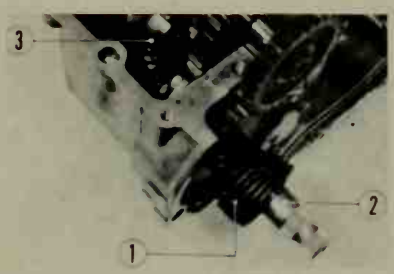


1. Referring to the preceding sections, remove the engine from the frame, remove the top end assembly, the left and right crankcase covers and all of the components therein.

2. The crankcases are horizontally mated. Remove the crankcase bolts which are located on both the upper and lower crankcase halves. The bolts are of different lengths; make a note of their location. Remove the upper crankcase half, tapping lightly with a plastic mallet to free it if stuck. The components will remain in the lower case half.

3. Lift out the crankshaft.

4. The gear clusters can be examined in place. If removal is desired, simply lift the clusters together out of the case.



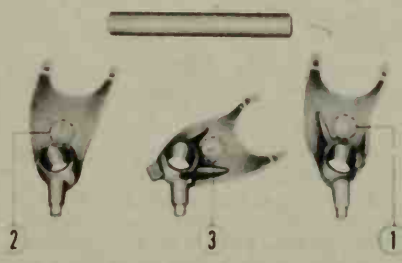
5. To remove the shift drum assembly, remove the shift fork shaft from the case. Remove the shift forks.

XL250 lower crankcase and shifter components

1. Center shift fork cam follower pin
2. Bearing set ring
3. Left gearshift fork
4. Right gearshift fork

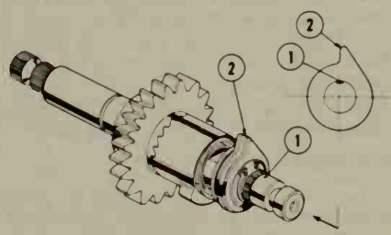
6. On the XL350/250, remove the cam follower pin clip and the cam follower pin from the remaining shift fork.

To remove the kick-starter, remove the stopper bolt (3), return spring (1), and pull out the shaft (2) (175)



7. On all models, remove the bearing retainer plate from the crankcase (left-side of the shift drum), and remove the shift drum from the crankcase.

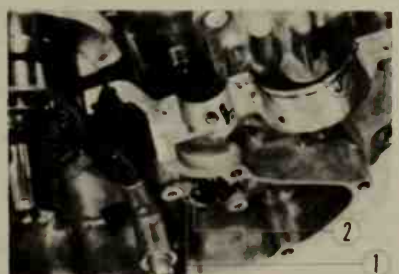
8. On the XL175, remove the kick-starter shaft by removing the kick-starter stopper bolt, the return spring, and pulling the kick-starter shaft out of the case. Disassemble the shaft by removing the circlip.



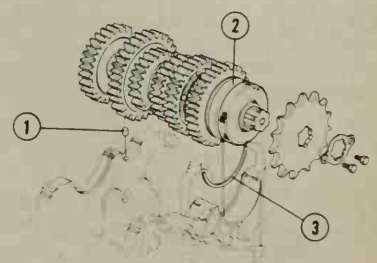
ASSEMBLY

1. Clean both case halves in solvent. Make sure that all oil passages are clear. Remove any traces of gasket compound from the crankcase mating surfaces. Be sure that all hollow locating pins are installed.

2. Install the crankcase components. Note that the shift forks are marked for position and must be installed in their original locations.

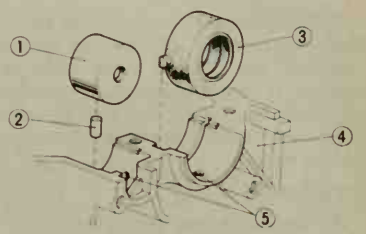


The shift forks are marked for position



When installing the 175 kick-starter shaft, be sure that the straight face of the kick-starter retainer pawl (2) is aligned with the mark on the shaft (1)

On the XL175, note that the straight face of the kick-starter retainer pawl should be aligned with the punch mark on the shaft. Further, the kick-starter assembly should be installed so that the pawl rests against the crankcase stopper.



3. Transmission shaft and crankshaft bearings are located either by set rings in the case halves, or by dowel pins. When installing the parts, be sure that the bearings are correctly seated in the case.

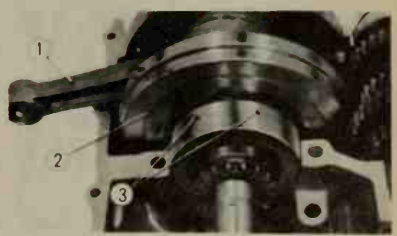
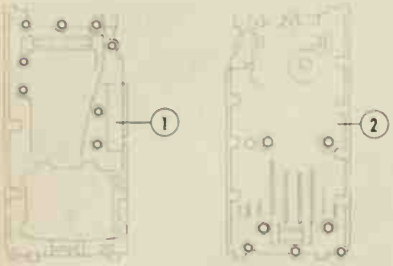
The countershaft oil seal (3) is equipped with a tab which must be installed in the slot in the crankcase (4). Note the mainshaft bearing (1) locating pin (2) and oil hole (5)

4. Note that the countershaft oil seal is equipped with a locating tab. This tab must be installed in the slot on the case provided for it. Failure to install the seal properly will result in blocking the oil supply to the gears.



5. Lubricate all bearings before assembling the cases.

6. Carefully apply a gasket sealing compound to the case mating surfaces. Do not overapply or excess will run down inside the cases when they are pressed together.

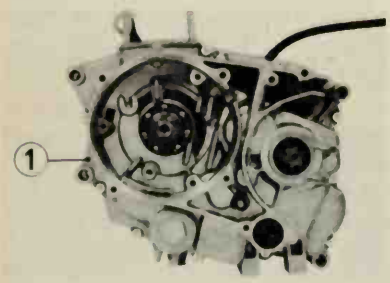


Crankshaft bearing locating pin

7. Ensuring that the hollow locating pins are in place, join the cases. Install and secure the crankcase bolts. Tighten these bolts in a criss-cross pattern until all are the proper torque. This is to avoid warping the cases.

Crankshaft bearing oil holes (3) must be clear

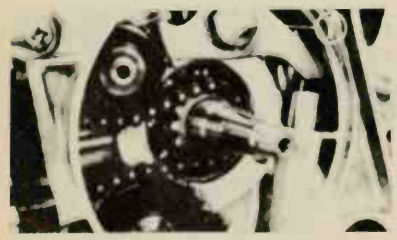
Upper (1) and lower (2) crankcase bolts (175). Tighten the bolts in a cross pattern



NOTE: *When the cases are first joined, they must mate all the way around without the need to force them together. If they will not, check the bearing locations. Make sure that the bearings are seated properly on their pins or set rings.*

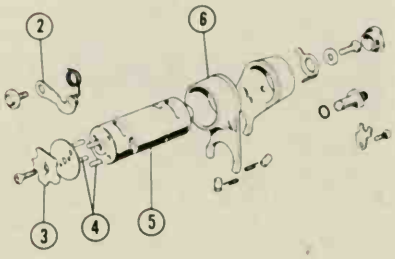
XL125/100/70

The crankcases are vertically mated.

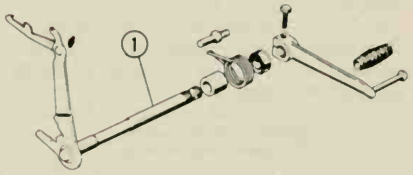


1. Remove the engine from the frame. Remove the cylinder head, cylinder, and piston. Remove the left and right-side covers and the components therein. Refer to the sections above for procedures.

2. XL125/100: Loosen the screws securing the crankcase halves (one screw is in the right cover, the remaining 10 are in the left) with an impact driver. Remove the screws. Separate the case halves. The crank and transmission will remain in the right crankcase half.



Crankcase screws (XL100)



3. XL70: Unscrew and remove the cam chain tensioner pushrod bolt, and remove the pushrod assembly. Remove the tensioner arm pivot bolt, and remove the arm and roller assembly. Remove the shift drum bolt beneath the rubber plug on the right crankcase half. Remove the eight crankcase screws, using an impact driver to loosen them, and separate the crankcase halves. The crank and transmission will remain in the left crankcase half.

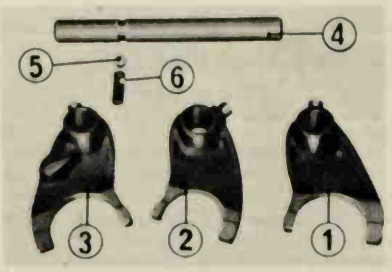
Tensioner arm pivot bolt (1) and arm (2) (XL70)

NOTE: *If the cases are stuck, they may be freed by tapping very gently with a plastic mallet. Do not strike the crankshaft or transmission shafts.*

Gearshift components: shifter shaft (1); stopper arm (2); stopper plate (3); shift drum pins (4); shift drum (5); shift fork (6) (XL70)

4. Remove the case gasket. Pull out the kick-starter shaft assembly.

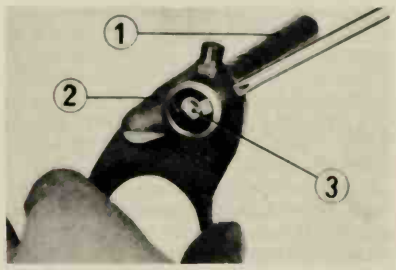
5. With care, tap the crankshaft out of the case. The case may be heated slightly with a propane torch in the vicinity of the crankshaft bearing boss to facilitate removal.



6. Very carefully remove the gear clusters and shift drum assembly as a unit.

7. On the XL70, the shift forks can be removed from the drum, if so desired, by removing the clips which secure the cam follower pins, and pulling out the pins. The forks will slide off the shift drum.

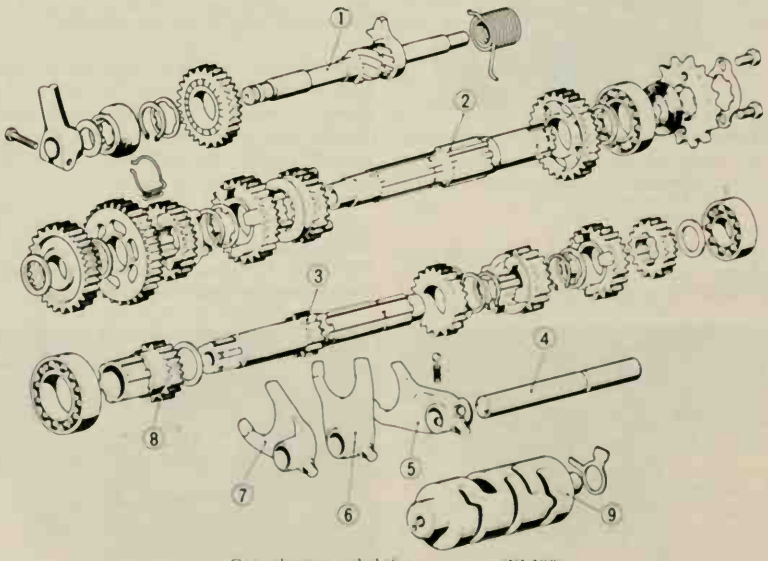
ASSEMBLY



1. Clean the crankcase halves thoroughly in a solvent, ensuring that all oil passages are clear. Clean the mating surfaces of any traces of old gasket. Be sure that the locating dowel pins are in place in the cases.

2. Assemble the shift drum mechanism if it was disassembled. On the

Gearshift forks (1, 2, 3), shaft (4), ball and spring (5 and 6)



100/125 models, the left gearshift fork is secured by a spring-loaded ball. To install, insert the spring and the ball into the shift fork, push the ball down with a thin screwdriver, and slip in the shaft. On the XL70, be sure that the cam follower pins are installed on the shift forks and secured with the clips.

Installing the shift fork shaft (1) in the fork (2) by compressing the ball and spring (3) with a thin screwdriver

3. Install the components into the case in the reverse of the removal procedure. Note the following points:

a. Install the crankshaft into the case

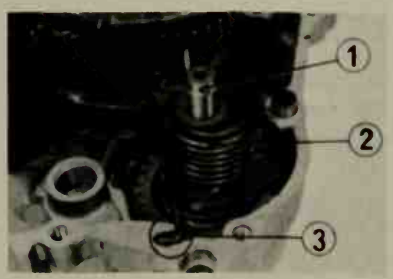
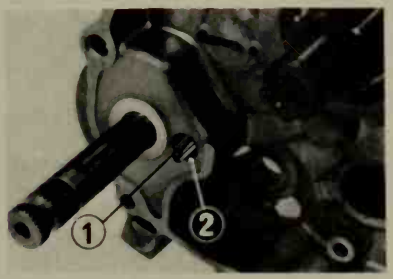
by pushing it straight in until the bearing is seated. Do not strike the end of the crankshaft to install it;

b. On the XL70, install the gear clusters and shift drum assembly as a unit;



Installing the gear clusters (XL70)



The neutral switch rotor (4) on the shift drum (3) should be parallel with the cylinder (about 10° from vertical) when installing the shift forks

c. On the XL125/100, install the gear clusters first, then the shift drum. Position the shift drum so that the neutral switch rotor would be parallel with the cylinder. This is equivalent to Neutral. Noting the locating marks on the shift forks, install the right, center, and left forks, in that order, engaging the cam follower pin of each fork with the proper groove in the shift drum. Then install the shift fork shaft;

When installing the kick-starter assembly (1), be sure that the end of the return spring (2, 3) is fitted into the cutout in the case

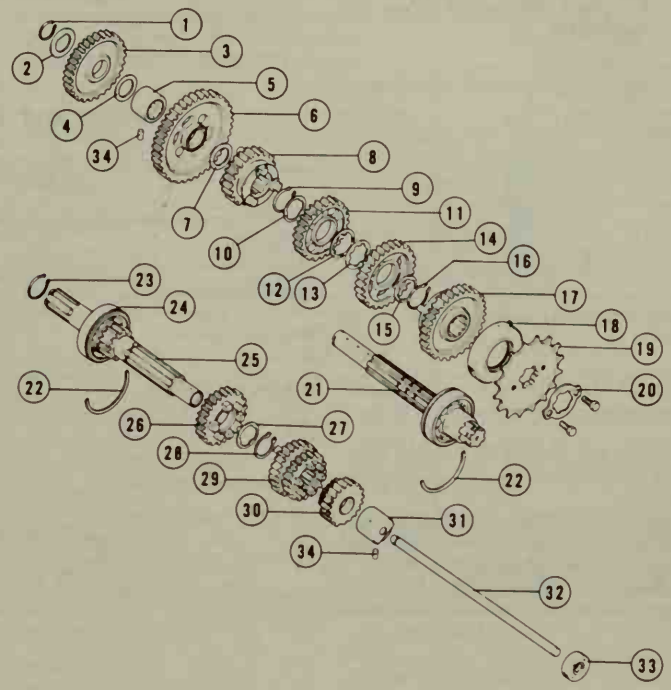
spring is seated in the crankcase. On the XL125/100, the retainer spring must protrude through the hole in the crankcase as illustrated;

e. Lubricate all bearings with motor oil;



f. Fit a new gasket. Ensuring that the transmission is in Neutral, assemble the case halves. Do not force the cases together. Install the crankcase screws and tighten them in a cross pattern to about 8 ft lbs;

NOTE: *Do not use the screws to mate the cases. This should be accomplished before they are tightened.*

g. Check for free rotation of the crankshaft and the gears.

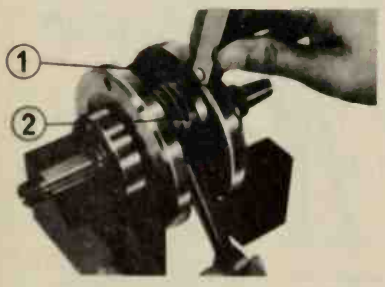
nent inspection is outlined in "Engine Rebuilding." Note the following:

1. On the XL350/250, if a new countershaft idler gear is fitted, check that the side clearance between the gear and thrust washer equals 0.60–0.75 mm (0.002–0.03 in.) If clearance exceeds 0.76 mm (0.03 in.), fit a new thrust washer 1.0 mm (0.04 in.) thick until clearance is correct.
2. Measure the thickness of the fingers and replace the fork if below the given specification.



Countershaft (1), thrust washer (2), idler gear (3) (XL350/250)

3. Check the shift fork cam follower pins for wear, and replace them if damaged.
4. Check the shift drum dowel pins. Replace any broken, worn or missing pins.
5. Measure the shift fork shaft diameter, the inside diameters of the forks, and compare to the standard specification.
6. Check the diameter of the drum and compare this to the standard specification.

CRANKSHAFT

The crankshaft is a pressed-together unit. The connecting rod big end bearing is the caged-needle type. In the event of damage to the con rod, bearing or crankpin, the crankshaft must be replaced as an assembly in most cases.

1. Lubricate the big end bearing with oil, and rotate the rod slowly around the crankpin. The movement must be smooth and silent.
2. With a dial gauge, check the up-and-down (radial) movement of the con rod. Compare the reading with the specification given. If rod movement is in excess of the specifications, the big end bearing is worn and the crankshaft must be replaced.

Checking con rod big end side clearance (2) with a feeler gauge (1)

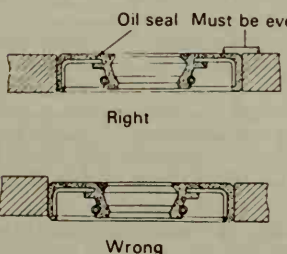
Checking transmission gear backlash

3. With a feeler gauge, check the clearance between the con rod big end and the crankshaft flywheel. Compare the measurement with the specification given for axial clearance.

4. Place the crankshaft on a set of V-blocks, or in the crankcase of models with horizontally-split cases, and check the crankshaft run-out with a dial gauge. Check both ends of the crank. Compare the run-out reading with the specification given for your model. If excessive, the crank must be replaced.

5. On the XL350, the connecting rod is stamped with a letter and the crankshaft with a number (1, 2, or 3). In the event that the con rod big end bearing must be replaced, check that the correct size bearing is used. Refer to the "Connecting Rod Bearing Selection" chart to determine the correct bearing to use. Bearings are numbered (—1 to —5).

BEARINGS AND SEALS



1. Bearings can be checked in place, whether on the crankshaft or in the cases. Be sure that the oil holes in the bearing races, if present, are clear.

2. Lubricate the bearing in question with some motor oil, and rotate it slowly. Movement must be smooth, effortless, and quiet.

3. If the bearing movement is halting or noisy, it should be replaced, note the following:

a. Crankshaft bearings must be replaced in pairs;

b. Ball bearings which remain in the crankcases (vertically-mated crankcase models) can be removed after prying out the oil seal (if fitted; the countershaft sprocket side bearing has an oil seal), heating the case gently with a propane torch, and tapping out the bearing.

Oil seal installation

4. Install new ball bearings by driving them straight into the case after the case

is gently heated. Avoid striking the inner race of the bearing. A bearing driver or a block of wood large enough to cover the whole bearing should be used. Be sure that the bearing is driven straight into the case, not cocked, and is properly seated.

5. Oil seals should be replaced as a matter of course. On models with vertically-mated crankcases, an oil seal can be pried out of the case with a screwdriver using a block of wood as a leverage point for the screwdriver to avoid nicking the case.

Seals with damaged or torn lips must be replaced, as must seals which have been pried out of a case.

6. When installing seals on models with vertically-mated crankcases, the seal should be pressed straight into the case using a drift large enough to cover the whole seal. Be certain that the seal is not cocked once in place and that the outer surface of the seal is flush with the crankcase surface.

7. Some seals, on models with horizontally-mated cases, may have a locating tab on them which must be fitted into a slot provided in the crankcase.

8. Grease the lips of all seals before inserting any shafts into them.

Lubrication System

All Honda XL series motorcycles are of the wet sump type. This means that the oil supply is contained in the crankcase sump rather than in an external oil tank. The oil is circulated under pressure by a single stage trochoid-type pump to the cylinder head components, right crankshaft bearing, connecting rod big end, and the transmission, on all models except for the XL70 where the transmission is lubricated by splash from the sump. Splash from the cam chain also lubricates the left crankshaft bearing.

The oil in the sump is picked up by the pump; it passes through the oil filter screen, then some is pumped to the transmission through the transmission mainshaft and the countershaft. The remainder of the oil is pumped to the right crankcase cover where some is sent through the centrifugal oil filter and then to the crankshaft bearings and the connecting rod big end bearing. The rest is pumped to the cylinder head to lubricate the cam bearings, rocker arms, and valves. The oil from the head then drains back into the sump through the cam chain passage.

This system supplies an unrestricted oil supply to the head and transmission, and freshly filtered oil to the crankshaft bearings and big end bearing.

OIL FILTER SCREEN

1. Drain the oil from the engine.
2. Remove the oil filter screen cap (except on XL70) and withdraw the filter spring and filter screen.

measure the clearance between the rotors and the straightedge; if the clearance between either rotor and the straightedge is more than 0.1 mm (0.004 in.), replace both rotors as a set. If clearance is still excessive after replacing the rotors, replace the pump body.

4. Assemble the pump and install the drive gear with the cutout on the shaft fitted into the inner rotor. Turn the pump by hand, it should turn freely.

5. Install the pump to the lower crankcase. Be sure that the three O-rings in the lower crankcase are in good condition.

6. Before operation of the motorcycle, remove the capnut from the cylinder head near the spark plug. If, after starting the engine, oil does not flow out within 12 seconds at 1,000 rpm with an oil temperature of 68° F, there is either an oil pump malfunction, clogged oil lines, or an oil leak. In cold weather the oil will take longer to flow.

Fuel System

Carburetor

Inspection procedures for the carburetor are outlined under "Carburetor" in "General Information."

REMOVAL AND INSTALLATION

XL350/250

1. Turn the fuel petcock to the "OFF" position, and disconnect the fuel line. Remove the fuel tank.

2. Remove the air cleaner and drain the float bowl.

3. Loosen the locknut on the cable adjuster and run the adjuster in to give as much slack in the cable as possible. Disconnect both the cables from the linkage. Disconnect the choke cable from the carburetor.

4. Loosen the band securing the carburetor to the intake manifold, and remove the carburetor by pulling it straight back.

5. Installation is in the reverse order of removal however be sure that the tab on the carburetor body is fitted to the slot located at the top of the intake manifold.

6. Adjust the free-play of the throttle cables as described in "Maintenance."

Other Models

1. Turn the fuel petcock to the "OFF" position. Disconnect the fuel line, and remove the fuel tank.

2. Remove the air cleaner and drain the float bowl.

3. Unscrew the top of the carburetor and withdraw the slide assembly from the top of the carburetor.

NOTE: *If the throttle slide assembly is not in need of servicing, it should be placed in a plastic bag secured with a rubber band to protect it from dirt, and placed out of the way.*

4. Remove the two bolts which secure the carburetor to the intake manifold, and remove the carburetor. Take care not to misplace the O-ring from the carburetor flange.

5. Installation is in the reverse order of removal. Be sure that the O-ring on the carburetor flange is in good condition.

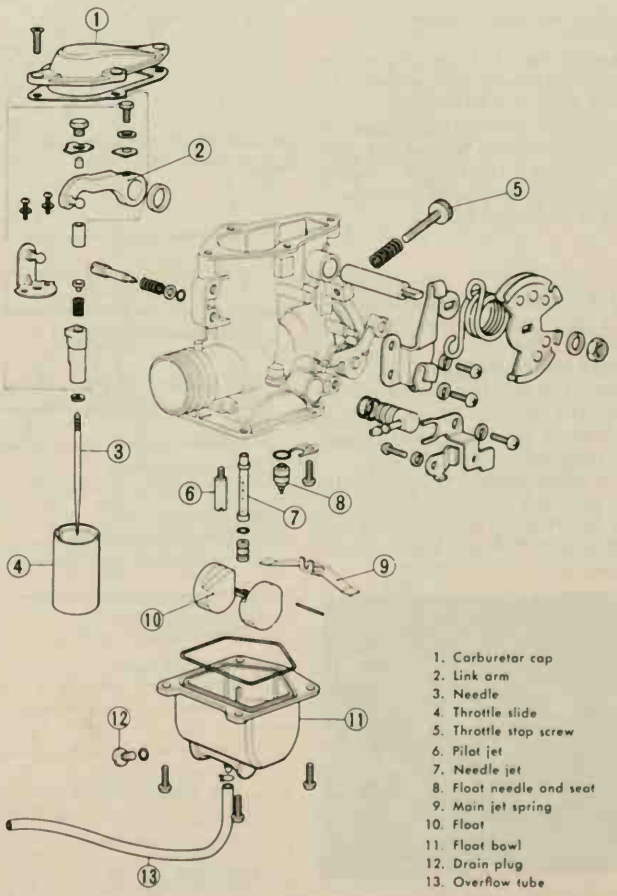
6. Tighten the mounting bolts evenly to avoid distorting the carburetor body.

7. When installing the slide assembly be sure to line up the slot in the slide with the tab inside the carburetor body. Be sure that the slide goes in easily, and especially that the needle enters the needle jet. Do not push or force the slide into place. If resistance is noted, it is probable that the needle is cocked to one side and is not entering the jet. Fit the carburetor cap in place and be sure that it is flush with the carburetor body before installing the ring nut to secure the cap in place.

Check throttle operation. The throttle return spring must have enough tension to snap the slide to the fully closed position if the throttle is opened and released.

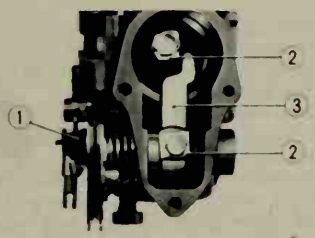
8. Adjust the throttle cable free-play as described in "Maintenance."

DISASSEMBLY



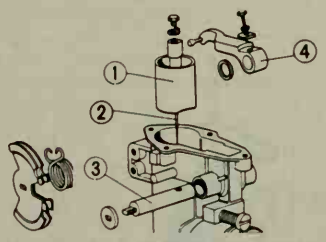
XL350/250

1. Remove the screws which secure the top cover to the carburetor body. Remove the top cover and cover gasket.



2. Remove the two bolts from the link arm after bending back the locking tabs.

3. Remove the 13 mm nut from the throttle shaft, and slip the throttle shaft out of the carburetor.



4. Remove the link arm and the throttle slide assembly from the carburetor. To disassemble the throttle slide assembly, disconnect the link arm, turn the

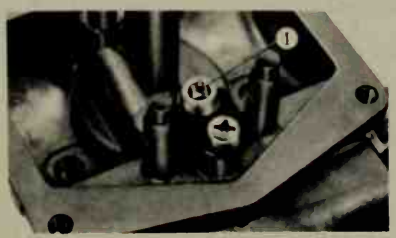
slide plate so that the tab on the plate is located in the slot in the throttle slide. In this position the plate can be lifted out.



5. The needle can be pushed out of the slide. If the clip is removed from the needle remember which groove it was located in so that it can be installed in the same groove so that the mixture is not changed. Moving the clip up on the needle will lean out the mixture while moving the clip down on the needle will give a richer mixture in the mid-throttle range.

6. Turn the carburetor upside down and remove the four screws from the float bowl. Tap the float bowl on the side to break the seal and remove the float bowl.

7. Remove the leaf spring and main jet on 250 models. Unscrew the main jet and jet holders on 350 models. Unscrew the pilot jet. Push the needle jet out from the top.

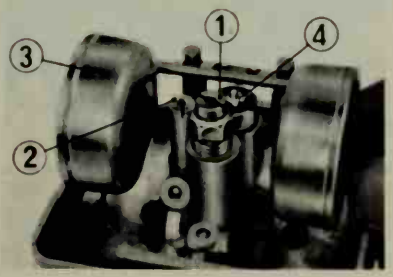
8. Remove the float pivot pin and remove the float and the float needle.

9. Remove the phillips head screw from the float needle seat set plate and remove the set plate and needle seat.



10. Remove the throttle stop screw and the pilot screw.

Other Models

1. To disassemble the throttle slide assembly, compress the spring against the carburetor cap, and slip the cable out of the slot in the side of the slide. Push the needle up and out of the slide noting the location of the needle clip.

2. Turn the carburetor upside down and remove the float bowl by swiveling back the retaining clip.

3. With a small drift push the float pivot pin out and remove the float and float needle.

4. With a small screwdriver remove the float needle seat, main jet, pilot jet, pilot air screw, and throttle stop screw.

5. Unscrew the main jet holder and with a small wooden dowel push the needle jet out from the top of the carburetor.

ASSEMBLY

XL350/250

Assembly is in the reverse order of disassembly, however note the following points:

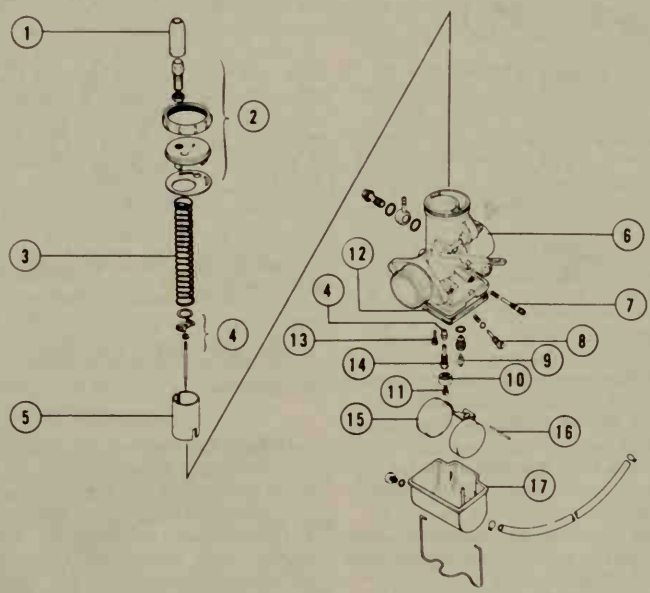
1. Replace any gasket or O-ring which is in less than perfect condition.

2. Install the float needle seat and secure it in place with the set plate and phillips head screw.

3. Install the pilot jet, and needle jet. On 350 models, screw in the needle jet holder, main jet holder, and main jet. On 250 models, press the main jet in place.

CAUTION: *Do not overtighten the jets, they are made of soft brass and are easily broken.*

4. Insert the float needle into its seat. Place the float in place and insert the float pivot pin.



5. On 250 models, place the leaf spring in place on the main jet.

6. Install the float bowl making sure that the O-ring is in good condition. Tighten the float bowl screws evenly so that a good seal is formed.

7. Install the needle in the throttle slide, making sure that the clip is in the same groove as it was found upon disassembly, unless tuning changes have been made.

8. Install the slide plate into the throttle slide, turn it to the proper position and secure it in place with two screws. Connect the link arm to the throttle slide assembly and install the assembly into the carburetor.

9. Slide the throttle shaft into place and replace the two bolts. Secure the two bolts in place by bending the locktabs up against the flat on the head of the bolt.

12. Install the throttle stop screw. Place your finger on the throttle slide and turn the screw in until it just starts to raise the slide.

13. Install the carburetor as described above. Start the engine and check for air leaks around the intake manifold, air cleaner, and carburetor top. Adjust the air screw and idle speed as described in "Tune-Up."

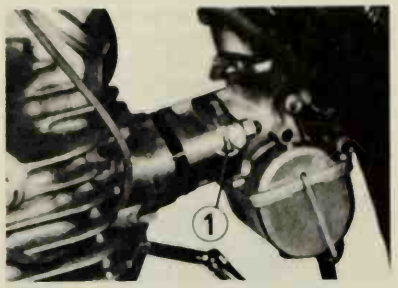
3. Screw in the float needle seat and the pilot jet.

CAUTION: *Do not overtighten the jets as they are made of soft brass which is easily broken.*



4. Drop the float needle into its seat, hold the float in position and slip the float pivot pin in place.

5. Place the needle in the slide making sure that the clip is in the same groove from which it was removed unless tuning changes have been made. Install the spring clip so that it is not covering the slot for the throttle cable.

6. Insert the throttle cable through the rubber cap, adjuster, ring nut, carburetor cap, rubber gasket, and spring. Compress the spring against the carburetor cap and slip the cable end pin in place in the slide.

7. Screw in the pilot air screw until it lightly touches its seat. Then back it out the number of turns listed for your model in the "Carburetor Specifications" chart at the end of this section.

8. Install the throttle stop screw and screw it in until it just starts to raise the slide.

9. Install the carburetor on the motorcycle. If the manifold was removed, be sure that the cutouts are facing the carburetor. Start the engine. Check for air leaks around the intake manifold, air cleaner, and carburetor top. Perform final adjustments as described in "Tune-Up."

MANIFOLD

Some 1976 models may have an atomizer plate fitted to the intake manifold. The plate needs no maintenance or service. If removed, however, it must be installed correctly. Refer to the illustration.

FUEL PETCOCK AND LINES

Cleaning

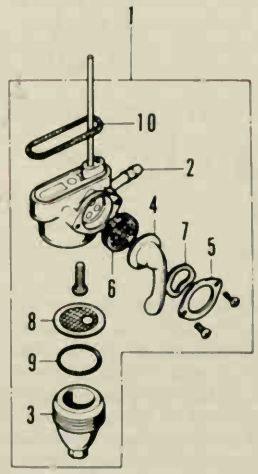
1. Turn the petcock to "STOP."

2. Unscrew the sediment bowl, remove the O-ring and filter screen.

3. Clean all the parts in solvent. Check that there are no holes in the filter screen and that the O-ring is not nicked or out of shape.

4. Run a little gas through the petcock to flush out any dirt (catch the gas in a suitable container). Use both the "ON" and the "RES" positions to check for operation.

5. Replace the filter screen, O-ring, and the sediment bowl.



Disassembly

1. Drain and remove the fuel tank.

2. Remove the sediment bowl, O-ring and filter screen.

3. Unscrew the phillips screws under the filter screen and remove the petcock from the fuel tank.

4. Remove the two screws from the fuel lever setting plate and remove the setting plate, lever spring, fuel valve lever, and fuel valve gasket.

Inspection

1. Clean all the parts in clean solvent and blow dry.

2. Inspect the petcock O-ring, sediment bowl O-ring, and fuel valve gasket for deterioration or cracks. Replace the O-ring if condition is doubtful. Inspect the lever spring for cracks or fatigue.

3. Inspect the fuel line for cracks or abrasion damage. Also, check the breather tube on the gas cap to make sure that it is clear. If a plastic fuel line is fitted as a replacement, check for brittle condition or discoloration. These are signs of age and if present, the fuel line should be replaced.

4. Be sure that the petcock can fully shut off the gas in the "stop" position.

Assembly

1. Install the fuel valve gasket, fuel lever, spring and fuel lever setting plate. Secure with the two screws.

2. Be sure that the petcock O-ring is properly seated and install the petcock on the fuel tank, securing it with the two mounting screws.

3. Install the filter screen, O-ring, and sediment bowl.

4. Install the fuel tank on the machine, connect the fuel line and breather hose. Before operation check the petcock for leaks.

Electrical Systems

XL350, 250, 175(76), 125, 125(76), and 70 models are equipped with magneto-type AC systems. With systems of this type, the battery is not a part of the ignition system. Current produced by the alternator (or "magneto") is supplied directly to the ignition coil. The battery powers the lights and electrical accessories.

The XL175, 125K1 and 100 use the standard battery ignition in which it is the battery itself which supplies current to the ignition coil. Charging of the battery is accomplished by the alternator.

Most of the electrical tests described below can be carried out with an ohmmeter or a continuity light, although a voltmeter and ammeter are required for some, such as alternator output tests.

Ignition Circuit

Hard starting or misfiring are often caused by ignition system troubles, but since electrical malfunctions are often trickier to pin down than carburetor faults, it is wise to ensure that systems other than the ignition are in serviceable condition before beginning any work.

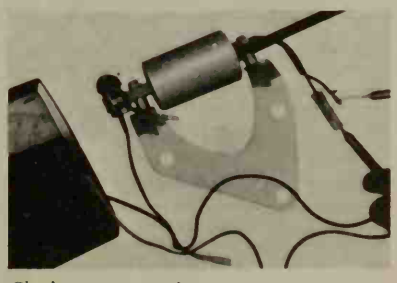
1. In the event of hard starting, misfiring, or cutting out, first check that all electrical connections are clean and tight.

2. On battery ignition machines, check the charge of the battery and recharge or replace it as necessary. Be sure that the battery terminals are clean and the connections secured tightly.

3. Check the ignition and kill switches for continuity.

4. Check the ignition timing for accuracy.

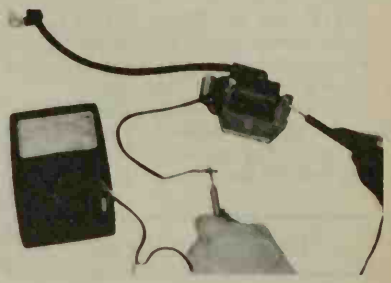
5. Remove the spark plug, clean it thoroughly, or replace it with a new one; gap the plug to 0.6–0.7 mm (0.024–0.028 in.). Connect it to its cap, and ground it against the cylinder head. Kick the engine over briskly. The spark produced should be thick and blue.



6. If there is no spark, or if the spark is weak and yellow, repeat the test using a piece of metal, such as a nail, inserted into the spark plug cap and held about ⅛ in. away from the cylinder. If the spark is healthy, the problem was the spark plug; if not, check the condition of the points. If excessive arcing or sparking at the points is noted while the machine is running, the problem may be the condenser. A defective condenser will also cause new points to wear out quickly.

7. If the problem is not in the points or the spark plug, the spark plug cap should be checked. Noise suppressor caps are fitted, which are designed to eliminate radio interference and provide a hotter spark by means of a resistor in the cap. Sometimes the resistor breaks down, and the cap then becomes an open circuit. Remove the cap from the spark plug lead, and hold the end of the lead about ⅛ in. from the cylinder head. If a fat, blue spark is produced when the engine is kicked over, the problem was the cap. Replace it with a new one.

8. If the cap checks out okay, carefully inspect the cable itself. Check for dirt or grease, cuts or cracks in the insulation, moisture, etc. If the lead is damaged, it must be replaced. This also involves replacing the coil.



9. If the trouble has not been pinpointed, the ignition coil windings should be checked for continuity, using an ohmmeter.

a. On battery ignition machines, disconnect the two low-tension coil leads and check for continuity between them. This is a check of the primary windings. If there is no continuity, replace the coil;

Checking ignition coil primary winding continuity (battery ignition)

b. On magneto ignition machines, check the primary winding by checking for continuity between the coil's low-tension wire (black or black/white) and the coil mounting plate. If continuity does not exist, replace the coil;

Checking primary winding continuity (magneto ignition)

c. On battery ignition machines, check for continuity across the coil's blue low-tension lead and the high-tension (spark plug) lead. Resistance may be very high, but continuity must exist. This checks the secondary winding;

d. On magneto ignition machines, check for continuity across the high-tension lead and the coil mounting bracket. If there is no continuity, replace the coil.

Even if continuity is present in the coil windings, it is possible that the coil is still defective. Replacing the coil temporarily with one which is known to be serviceable is recommended.

10. The condenser can be checked if a capacitance tester is available. Condensers should have a capacitance of approximately 0.25 mf. Checking with a "megger" (high-voltage ohmmeter) should yield a resistance of 10M ohms at 1,000V.

As noted above, sparking at the points, or points which pit or burn rapidly would indicate a defective condenser. Bad condensers will cause mounds and matching depressions on the points.

On battery ignition machines, the checks above cover all ignition circuit components and the trouble should be evident. On magneto ignition bikes, the magneto itself must be checked if the cause of the problem has not yet been determined.

Assuming that all other ignition circuit components have been eliminated as the possible trouble spots, and the ignition and kill switches have been checked, proceed as follows:

1. Remove the left crankcase sidecover and the magneto rotor. A special puller must be used to remove the rotor.

2. Check the rotor for any score marks which would indicate that the rotor is contacting the core ends. If so, the condition must be remedied. If this has occurred, check for any play in the crankshaft which would indicate a bad crankshaft bearing. Other reasons may be improper mounting of the coil cores or rotor, worn crankshaft taper, or rotor taper surface. If the taper is damaged, the rotor should be replaced. Also inspect the

rotor for any cracks or fractures. If present, replace.

3. Check for continuity between the black or black/white wire and ground. If continuity does not exist, the primary exciting coil is either broken internally, or is poorly grounded.

NOTE: *On the XL70, if this test is made with the coils still on the engine, be sure that the points are open or held open with a bit of thick paper.*

4. Check the resistance between the coil core and the mounting plate or crankcase cover. The coil core should be well grounded (no resistance).

Charging Circuit

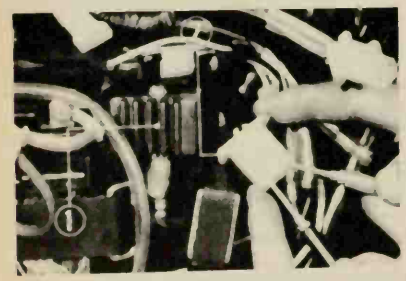
XL175/125K1/100

1. In the event that the battery overcharges, check the battery itself, and the voltage regulator (XL175 before 76).

2. If the battery discharges quickly, or fails to hold a charge, check the battery, the regulator, rectifier, and alternator.

Voltage Regulator (XL175 before 76)

A voltmeter is needed to check the regulator.

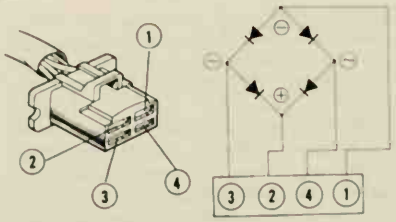


1. Ensuring that the battery is in good condition (no shorted cells) and fully charged, connect a voltmeter across the battery terminals. Start and run the engine to 1,000 rpm. The voltmeter should read 6–7 volts.

2. If the voltage reading is low, disconnect the three voltage regulator leads, and repeat the test. If voltage increases to the proper value, the regulator is defective.

Rectifier

An ohmmeter or a continuity tester (low voltage) is used to check the rectifier. Do not use a megger.



1. Disconnect the rectifier leads at the plastic connector. There are four leads wired to the connector. This rectifier is the full-wave type, consisting of four diodes wired as shown in the illustration.

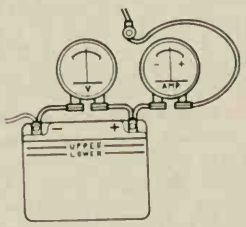
Checking the rectifier (1) with a continuity tester at the leads (2)

To check the rectifier, you will be checking each diode in turn to ensure that current will flow through each in one direction only. Current flow in both directions, or no current flow in either direction through a diode indicates that it is defective.

2. Imagine that the four leads are numbered 1 through 4; connect the negative lead of the tester to the No. 1 rectifier

Rectifier leads

1. Green
2. Red/white
3. Yellow
4. Pink



wire. Connect the positive tester lead to the Nos. 2, 3, and 4 wires in turn. Note whether or not there is continuity. Now reverse the connections so that the positive tester lead is connected to rectifier wire No. 1, and the negative lead to wires Nos. 2, 3, and 4 in turn.

Continuity should exist in one direction only for each pair of connections. If continuity exists in both directions, or in neither direction, the rectifier is defective.

3. Repeat the test using all possible combinations of wires: 2–4, 2–3, 3–4, and their reverse. Replace the rectifier, if, in any case, it shows continuity in both or neither direction for a pair of wires.

Alternator

1. A dynamic test may be carried out if a voltmeter and ammeter are available. The battery must be fully charged. Hook up the voltmeter across the battery terminals, and the ammeter to the positive terminal of the battery and to the red/white lead, as shown.

Voltmeter and ammeter connections to check alternator output

2. Start the engine and note the voltmeter and ammeter readings at the given rpm and compare them to those given in the "Charging Characteristics" chart for your machine. If the readings are not within the proper specifications, the stator coil should be removed from the machine and checked for continuity as outlined below.

Charging Characteristics

Lights	Beginning of Charging	5000 rpm
XL175, XL100		
Off	6.8v 1000 rpm	7.8v/1.3a
On (high beam)	6.8v 3500 rpm	7.2v/0.2a
On (low beam)	6.8v 2200 rpm	7.8v/1.3a
XL125K1		
Off	6.8v 1000 rpm	6.8v/1.7–2.3a
On	6.8v 3000 rpm	6.8v/0.5–1.1a

3. Check for continuity between all three stator leads. Continuity must exist, or the stator assembly has a broken wire and it must be replaced.

4. Check for continuity between the yellow lead and the stator core. If continuity exists, there is a short, and the stator must be replaced

XL125 AND XL125(76)

These models were fitted with an alternator and magneto ignition. There is no voltage regulator, and the rectifier is the simple half-wave type.

1. For a check of alternator output, hook up the voltmeter across the battery terminals and the ammeter between the positive battery terminal and the red lead, as directed for the 175/125K1/100, above. Output should be approximately the same as shown for the 125K1.

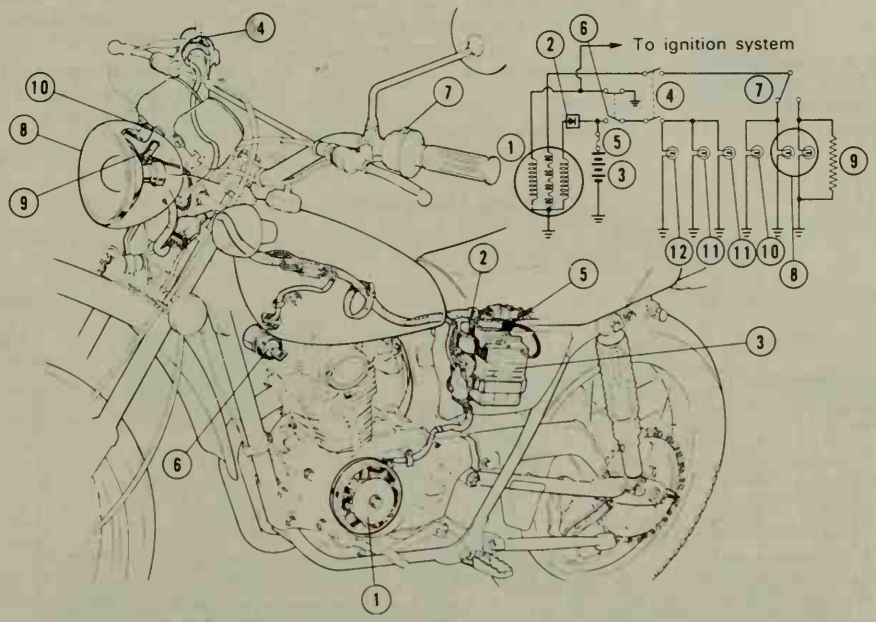
2. To check the alternator stator coil, use an ohmmeter to check for continuity between the leads and the stator core. The black stator lead is the ignition coil lead. The yellow lead is for the lighting coils, and the white lead is the battery charging coil.

3. Continuity should exist between all three leads and the stator core. If it does not, suspect a broken coil wire.

4. To check the rectifier, check for current flow across the rectifier terminals in both directions. Current must flow in one direction only. If current flows in both directions or in neither direction, replace the rectifier.

XL350/250

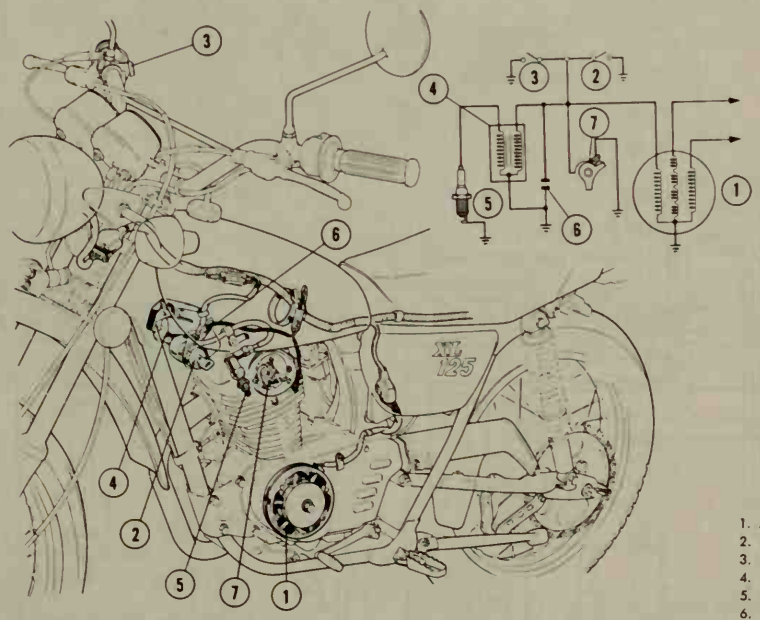
1. Checking of the voltage regulator may be carried out as outlined for the XL175, above.



2. The rectifier used on these models is quite similar to that found on the XL175/125K1/100, although the wiring is slightly different. Testing is accomplished in the same way: check for continuity between each pair of leads, then reverse the tester connections and check again. Current will flow in only one direction. (See above.)

3. A dynamic alternator test can be carried out after disconnecting the regulator if a voltmeter and ammeter are available. Hook these up as outlined under the XL175/125K1/100 alternator test section, and compare the meter readings at the various rpm to those given in the "Charging Characteristics" chart.

Charging Characteristics



Lights	Beginning of Charging	5000 rpm	8000 rpm
XL350, XL250			
Off	6.3v 1000 rpm	8.0v/1.5a	8.9v/4.0a
On	6.3v 2500 rpm	7.5v/1.2a	8.3v/1.3a

4. The stator assembly can be checked with an ohmmeter. Resistance between the black/white or black lead and ground on the stator body should be about 2.3 ohms. Between the white/yellow lead or white lead and the stator: 0.36 ohms, and between the pink lead and the yellow lead: 0.57 ohms.

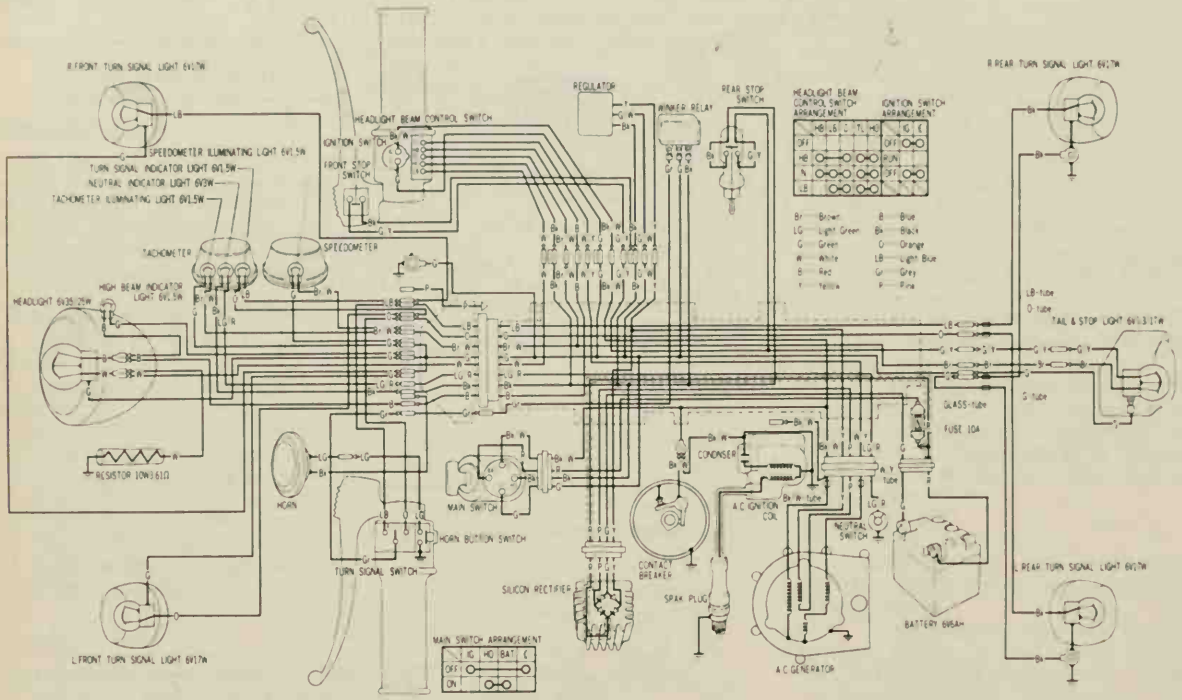
XL70

Rectifier

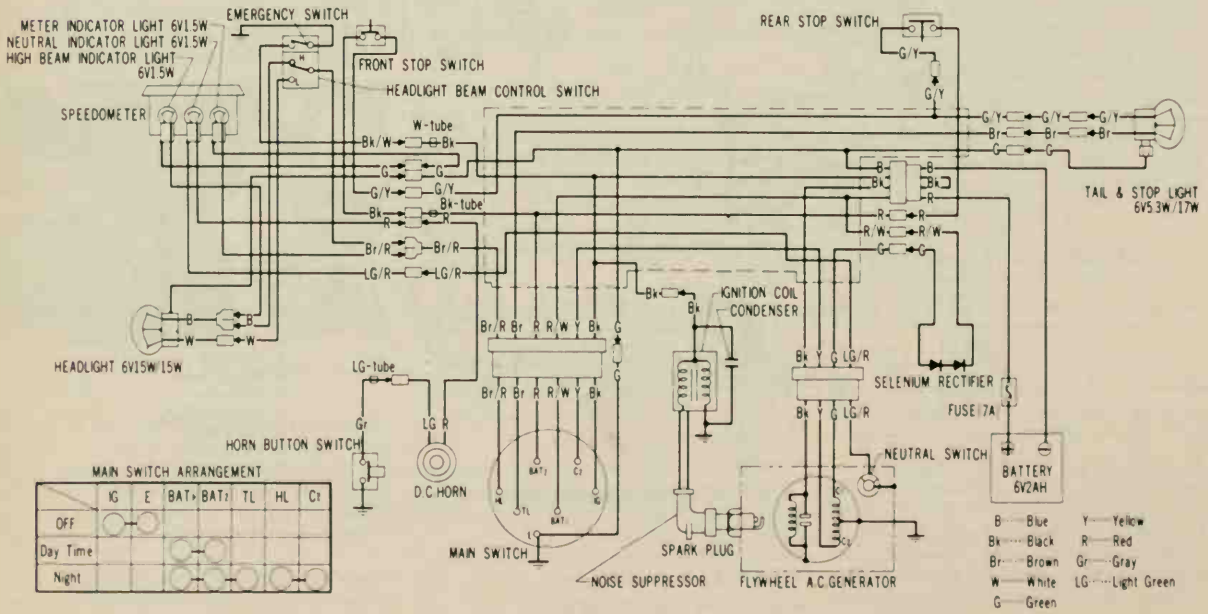
1. The rectifier is a simple half-wave unit which has two leads (red/white and green). To check the rectifier, disconnect these leads, and connect a test light or ohmmeter across the rectifier terminals. Note whether or not continuity exists. Now reverse the leads and note whether or not there is continuity.

2. There must be continuity in one direction only. If there is continuity in both directions or neither direction, the rectifier is defective.



Alternator

1. To check the lighting coils, use an ohmmeter or continuity light.



2. Disconnect the alternator wiring at the plastic connector. Check for continuity between the green lead and ground on the engine case. Check for continuity between the yellow lead and ground.

Check for continuity between the green and the yellow leads. Continuity must exist in all three cases or the lighting coil must be replaced.

Wheels

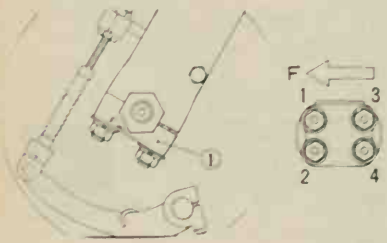
REMOVAL AND INSTALLATION

Front Wheel

XL350/250

1. Support the front wheel off the ground by placing a crate or another suitable object beneath the engine.

2. Loosen the locknut on the front brake cable adjuster and run the adjuster nut up to give as much slack in the cable as possible. Remove the cotter pin on the hub brake lever and disconnect the cable from the brake lever and the brake plate.



3. Remove the phillips head screw from the speedometer drive housing and disconnect the speedometer cable.

4. Remove the eight axle capnuts (four on each fork leg).

NOTE: *Before removing the nuts, place a block of wood under the tire to keep the weight of the wheel off the axle caps as the nuts are loosened.*

5. Remove the block from under the tire, letting the axle drop below the studs on the fork legs. Remove the wheel.

6. For installation: hold the wheel in place with the brake plate anchor engaged in the fork leg. Install the axle caps with the "F" mark toward the front. Place a flat washer, lockwasher, and nut on each stud in that order. Position the speedometer drive housing so that the speedometer cable will fit into it without excessive bending.

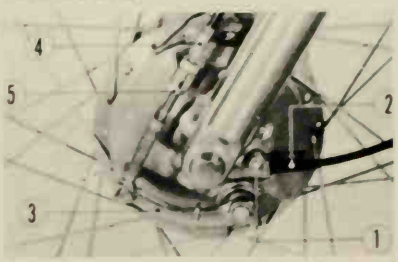
Be sure that the axle cap (1) is installed with the gap at the rear. Note the tightening order

7. Tighten the nuts, starting with the outside front, then the inside front followed by the outside rear and the inside rear. Tighten the nuts to a torque of 13.0–16.6 ft lbs.

NOTE: *When all the nuts are tightened properly the axle caps and the fork sliders should be touching in the front with a small gap in the rear.*

8. Install the front brake cable. Secure the cable to the brake lever with a new cotter pin. Adjust the brake as described in "Maintenance."

9. Line up the slot in the end of the speedometer cable with the tab in the speedometer drive housing by rotating the wheel slowly. Install the speedometer cable and secure it in place with the phillips head screw.



ALL OTHER MODELS

1. Support the front wheel off the ground by placing a crate or similar object beneath the engine.

2. Loosen the locknut on the cable adjuster and run the top adjusting nut up to give as much slack in the cable as possible. Remove the cotter pin from the brake lever on the brake plate and disconnect the cable from the lever and brake plate.

3. Remove the phillips head screw from the speedometer drive housing and disconnect the speedometer cable.

4. Remove the cotter pin from the axle nut. Remove the axle nut and washer (a phillips head screwdriver may be placed through the left-side of the axle to keep it from turning while unscrewing the nut). Using the screwdriver, pull the axle out and remove the front wheel assembly from the forks.

Remove the speedometer cable screw (1), pull out the cable (2) and disconnect the adjuster (4 and 5) from the brake lever (3) (175 shown)

5. To install, hold the wheel between the forks engaging the brake plate anchor with the left fork leg. Slip the axle in place from the left-side. Position the speedometer drive housing so that when the speedometer cable is attached it will not be bent excessively. Keeping the axle from turning with a screwdriver, install the washer and axle nut. Torque the nut to 39.8–47.0 ft lbs then back it off until a slot in the nut lines up with a hole in the axle. Secure the axle nut in place with a new cotter pin.

6. Install the front brake cable to the brake lever and then to the brake plate. Secure the cable end pin in place with a new cotter pin. Adjust the cable as outlined in "Maintenance."

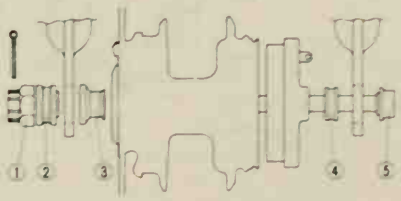
7. Line up the slot in the end of the speedometer cable with the tab in the speedometer drive housing by slowly rotating the wheel. Install the speedometer cable and secure it in place with the phillips head screw.

Rear Wheel

ALL MODELS

1. Raise the rear wheel off the ground by placing a crate or another suitable object under the engine.

2. Remove the cotter pin, securing nut, lockwasher, and flat washer from the brake anchor at the brake plate.

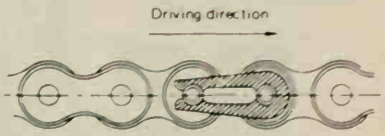


3. Remove the cotter pin and axle nut from the left-side of the axle.

4. Remove the rear brake adjusting nut from the end of the brake cable or rod and disconnect the cable (or rod) from the brake lever.

5. Remove the masterlink from the drive chain. Place the masterlink on the end of the chain for safekeeping. If the chain doesn't have a masterlink, loosen the chain adjuster locknuts and run the adjusters in. Move the wheel forward in the swing arm and slip the drive chain off the rear sprocket. If the chain won't come off the sprocket, it will have to be broken with a special tool.

6. Pull the axle out from the right-side and remove the wheel assembly from the swing arm.



NOTE: *Place the wheel spacers on the axle in the order that they are removed, and screw the axle nut on the axle for safekeeping.*

7. To install the wheel: wrap the drive chain around the rear sprocket. Hold the wheel in place and slip the axle in place from the right-side. Be sure that the spacers are in their correct locations. If the masterlink was removed, place both ends of the chain on the rear sprocket and install the masterlink with the open end of the spring clip facing opposite the direction of rotation.

Install the masterlink spring clip with the closed end facing the direction of chain rotation

8. Engage the brake anchor with the brake plate and secure with the flat washer, lockwasher, and the nut. Install a new cotter pin in the brake anchor bolt.

9. Turn the axle nut on finger-tight. Adjust the drive chain slack; the slack, measured midway between the sprockets, should be about ¾ in. Refer to "Maintenance" if necessary.

10. Slip the brake cable or brake rod through the fitting in the brake lever and install the adjusting nut. Adjust the cable so that the brake pedal has 1 in. free-play before the brake shoes contact the drum.

11. Tighten the axle nut to the proper torque, which can be found in the "Chassis Torque Specifications" chart at the end of this section. Then back the nut off until a slot in the axle nut is lined up with a hole in the axle. Secure the axle nut in place with a new cotter pin.

WHEEL DISASSEMBLY

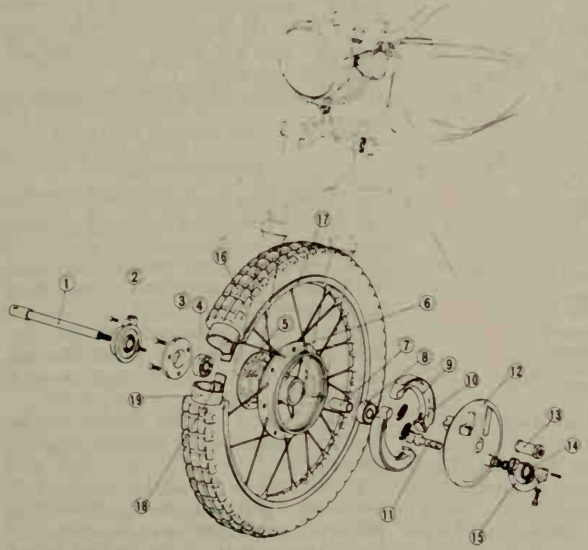
Front Wheel

XL350/250

1. Remove the wheel from the machine as previously described.
2. Place the wheel assembly in a vise secured by the axle nut, or secure the axle nut with a suitable wrench. Slip a phillips head screwdriver through the hole in the right-side of the axle and remove the nut.
3. Remove the axle, speedometer drive housing, and brake plate.
4. Remove the cotter pin and washer from the upper brake pivot, and spreading the brake shoes by hand remove the shoes complete with their springs from the brake plate.

Removing the linings from the brake plate

5. Remove the pinch-bolt from the brake lever and remove the brake lever, return spring, plain washer, and dust seal. Push the brake cam out of the brake plate.
6. Remove the three phillips head screws from the bearing retainer plate located on the right-side of the hub. Remove the retainer.
7. With a suitable drift and hammer tap out the wheel bearings. Gentle heat can be used around the bearing bosses in the hub to facilitate removal. Take care not to score the hub where the bearings seat. The spacer tube can be removed once one of the bearings is removed.



ALL OTHER MODELS

1. Remove the front wheel from the motorcycle as previously described.
2. Remove the brake plate. Remove the cotter pin and washer from the upper brake pivot (XL175). Spread the brake shoes by hand until they will clear the brake cam, remove the shoes complete with the brake springs from the plate.
3. Remove the pinch-bolt from the brake lever and remove the lever, return spring, flat washer, and dust seal. Push the brake cam out of the brake plate.
4. Remove the wheel spacer from the right-side of the hub. Remove the oil seals from the right-side of the hub and the inside of the brake plate. These seals can be pried out with a hooked tool as new seals should always be used on reassembly. However take care not to score the hub surface.
5. Using a propane torch, gently heat the area around one of the bearings. Turn the wheel assembly over, placing it on a bench so that the heated side faces down.
6. With a suitable drift and hammer, tap out the bearing. The spacer tube will also come out after the bearing is removed.
7. Turn the wheel over, and heat the hub in the vicinity of the other bearing as was done previously. Tap this bearing out in the same manner.

INSPECTION

All Models

BRAKES

1. Clean all parts thoroughly in a suitable solvent, making a special effort to remove the dust and built-up dirt from the brake plate.

2. Inspect the shoes for wear. There should be at least 0.10 in. (2.5 mm) of lining material left (measured at the lining's thinnest point) or the shoes must be replaced.

3. Inspect the linings for scoring or grooves. These may be caused by particles of dirt which enter the drum. If badly scored, the shoes should be replaced and the drum inspected closely for the same type of damage.

Be sure that the linings are free of any oil or grease. Impregnated linings must be replaced.

4. If the linings are in usable condition, rough up the surface with coarse sandpaper. Then, clean the linings with alcohol, or lacquer thinner. Clean the brake drum with the same solvent.

5. Check that the brake lever pinch-bolt is not bent. Replace it if this has occurred. Replace the brake lever if the splines are worn or broken.

6. Inspect the splines on the brake cam. These should be in good condition. The cam must rotate freely in the brake plate passage. If it does not do so, use a fine grade of sandpaper on both the cam and the surface of the passage.

7. Check the condition of the brake springs. Replace them if weakened, rusted, or deformed.

8. Check the brake plate for cracks or fractures.

BRAKE DRUMS

1. Upon disassembly of the hub, inspect the brake drum surface for condition. The drums must be clean and free of score marks or rust. Check the diameter of the drum and compare with the specification given at the end of this section.

2. Rust can be removed from the drum surface with sandpaper. Polish the surface until it is shiny, then clean it thoroughly.

3. Alcohol or lacquer thinner can be used to remove dirt or deposits from the drum.

4. The drum should be checked for concentricity. An out-of-round condition is usually noticeable as an on-off-on feeling when the brake is applied while riding. With the wheel assembly mounted on the machine, spin the wheel while applying the brake very lightly. The rubbing noise of the brake against the drum should be heard for the entire revolution of the wheel.

5. An out-of-round condition and most scoring can be removed by having the drum turned on a lathe. This operation

should be entrusted to a qualified specialist with the proper equipment. Usually, the tire and wheel bearings will have to be removed so that the wheel can be chucked in the lathe. If the rim needs to be trued, have this done before any work on the drum is performed, as the action of the spokes while truing the rim may further aggravate the drum warpage.

Cushion Hub

When the sprocket and the drive flange are removed, check the condition of the rubber dampers in the hub. Replace them if they are worn, cracked, or hardened. The dampers must not allow the drive flange to move more than ½ in. in the hub. This reading is taken by placing the flange in the hub and noting the total movement of the rim of the flange relative to the rim of the hub in the plane of wheel rotation. If movement exceeds ½ in., the dampers should be replaced.

Wheel Bearings

1. Clean the bearings, and spacer tube in a suitable solvent, removing all of the old grease. Clean out the hub as well.
2. Check the bearing bosses in the hub for scuffs, cracks, or distortion. If they are in any way damaged, the hub must be replaced.
3. Check the condition of the spacer tube, and replace if damaged.
4. Bearing condition is very important. Check the ball themselves for pitting, wear, or rust.
5. Apply a few drops of light oil to the bearing and spin it. The bearing must rotate smoothly and freely. Any roughness or binding in rotation will necessitate new bearings.
6. Place the bearing on a flat surface. Place your fingers on the outer bearing race to hold it steady. Attempt to move the inner race back and forth. In a good bearing, the race will spin, but not move in any other direction. If it does, the bearing must be replaced.
7. Note that the bearings must be replaced in pairs.

WHEEL ASSEMBLY

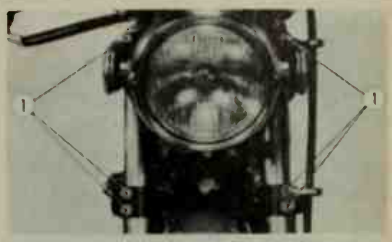
All Models

Assembly is in the reverse order of disassembly; however, note the following points:

1. Obtain a good grade of wheel bearing grease to lubricate the wheel bearings.
2. Pack the wheel bearings until they are completely filled.
3. Drive one of the bearings into its seat. Put a quantity of wheel bearing grease into the hub. Install the retainer if so equipped. Install the spacer tube and drive the other bearing into its seat. The sealed surface of the bearing must face the outside of the hub.

Bearings should be installed with a block of hard wood as a drift. Do not strike the inner race of the bearing when installing it. Tap around the outer race until the bearing is straight in the hub, then drive it straight in.

NOTE: *When a bearing retainer is fitted, the bearing with the retainer should be installed first. Then install and tighten the retainer, spacer tube, and the other bearing.*



4. Replace all of the oil seals with new ones. Like the bearings, the seals should be pressed straight in.
5. Coat the surface of the brake cam with chassis grease before installing it into the brake plate.
6. Lubricate the brake shoe pivot points with chassis grease. Take care not to allow any grease to come into contact with the surface of the brake shoes or drums.
7. Line up the slots in the speedometer gear with the slots in the wheel hub.
8. Install the brake lever on the brake cam so that the punch marks on the brake lever and the brake cam are lined up.

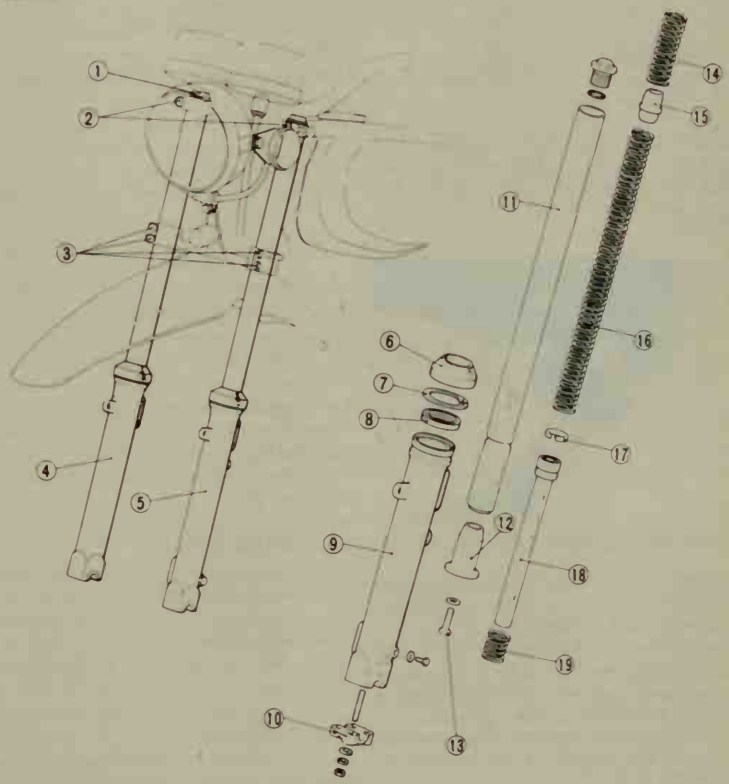
Front Forks

REMOVAL

All Models

1. Loosen the fork filler caps located at the top of each fork leg.
2. Support the front wheel off the ground by placing a crate or another suitable object beneath the engine.
3. Remove the front wheel. Remove the fender.

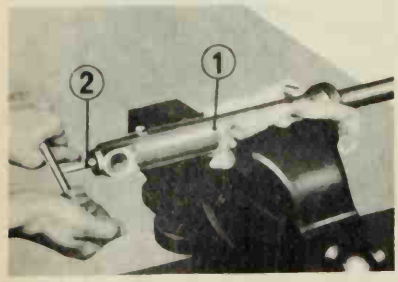
Upper and lower triple clamp pinch-bolts



4. Loosen the pinch-bolts on the upper and lower triple clamps, and remove the fork legs one at a time by pulling them straight down. If the fork legs resist removal, spread the lower triple clamp with a wedge and tap the fork leg out with a soft faced mallet.

DISASSEMBLY

All Models (Except XL70)



The procedure is given for one fork leg, but it applies to both.

1. Remove the filler cap from the top of the fork tube and pour the oil into a suitable container to be disposed of.
2. Remove the spring(s) from the top of the tube.
3. Turn the fork upside-down and rest it on a block of hard wood. With an impact driver and the proper bit remove the allen bolt from the bottom of the slider. These bolts are installed with thread

A strip of copper or other soft metal can be used between the top of the slider and the handle of the wrench to protect the slider.

The procedure is given for one fork leg, but it applies to both.

1. Remove the filler cap from the top of the fork leg and pour the oil into a suitable container to be disposed of.

INSPECTION

All Models

1. Wash all metal parts in a solvent and dry.

2. Inspect the fork slider for cracked, broken, or distorted axle brackets, worn inner bore surfaces, damaged threads, or dents which have affected the inner bore. Replace the slider if defective in any of the above ways.

3. Inspect the fork tubes for condition: the chrome plating must be intact throughout. Check for damaged threads, and worn or scuffed inner or outer surfaces. Check the tubes for straightness. This is done by placing the tubes in a set of V-blocks and checking the run-out with a dial gauge. If the tube is bent more than 0.060 in. as indicated by the gauge, it must be replaced.

4. Inspect the piston ring for wear or scoring.

5. Check the filler cap O-ring for cracks or any other signs of wear; replace it if damaged.

6. Check the general condition of the fork springs. Replace any which are badly rusted, have collapsed coils, etc. Compare the lengths of corresponding springs. They should be of approximately

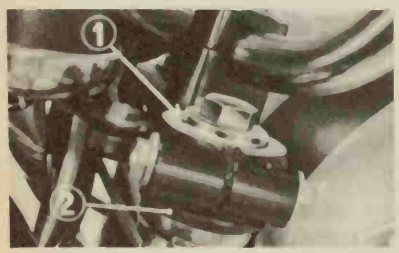
ASSEMBLY

All Models (Except XL70)



1. Be sure that the piston is in the slider. Lubricate the new oil seal with ATF and install it into the top of the slider. Place a block of hard wood over the seal and drive it straight into the slider as far as possible. Then place the old seal on top of the new one and drive them in until the new one clears the snap-ring groove in the slider. Take out the old seal. Be sure that the new seal is straight in the slider. The distance from the top of the oil seal to the snap-ring groove should be the same all around the seal. Install the snap-ring. Lubricate the lips of the seal.

2. Install the rebound spring and damper rod in the fork tube. Carefully install the slider on the tube. Replace the fork spring(s) and cap temporarily. Turn the fork upside down and install the bolt in the bottom of the slider. The threads of this bolt should be coated with thread locking compound.

3. Fit the drain plugs; be sure to install the gaskets.

5. Remove the cap and fill the forks with the proper amount of ATF. Note that the amount added to rebuilt forks will be slightly more than for a normal fork oil change (15–20 cc/0.5–0.6 oz more).

6. Refit the fork tubes through the triple clamps. The top of the fork tube should be even with the top of the upper triple clamp except on the XL250 where the front forks are adjustable. On the XL250, both forks should be adjusted the same to either the high or standard position.

Install the top of the fork tube (1) flush with the top of the upper triple clamp (2)

7. Tighten the pinch-bolts on the lower triple clamp, and then tighten the fork filler caps and the pinch-bolts on the upper triple clamp, in that order.

8. Fit the front wheel and check the operation of the forks.

1. Install a new oil seal on the fork tube. Be sure to lubricate the seal with ATF before placing it on the tube.
2. Install the sliding bushing on the tube with the flange on the bushing fac-

ing the top of the tube. Install the two circlips, piston, and bottom circlip. All of the circlips must be a snug fit on the fork tube, if not replace them. Slide the fork spring into the tube from the bottom
3. Place the fork tube into the slider and drive the oil seal into its seat in the top of the slider. Replace the washer, snap-ring, and dust seal.
4. Fill the fork leg with the proper amount of ATF: 3.7 oz/110 cc. Replace the top washer, O-ring, and filler cap.

Steering Stem Assembly

BEARING ADJUSTMENT

1. The steering stem bearings are uncaged #6 (XL125/100/70) or #8 (XL350/250/175) steel balls. They are adjusted by means of a ring nut beneath the upper triple clamp.
2. To check bearing adjustment, support the front wheel off the ground. Grasp the fork sliders with both hands.
3. Attempt to move the forks by pulling out on the sliders. If play or movement can be felt, the bearings are too loosely adjusted or worn.
4. Turn the forks slowly from lock-to-lock. Movement should be smooth, silent, and effortless. If any binding or uneven movement is felt, the balls and the races are either too tightly adjusted or are worn. If the steering feels uniformly stiff, the bearings are too tightly adjusted. If any noise is noted, the bearings are damaged, or some are missing.
5. With the front wheel off the ground, release the front forks from a few degrees off the centered position. The forks should fall freely to either side of their own weight. If they will not, the bearings are too tightly adjusted, the steering stem is bent, the races are extremely worn, or some of the bearings are missing.
6. Bearings can be adjusted with a hammer and punch or pin wrench on the adjuster nut under the upper triple clamp after the triple clamp is removed. To do this, remove the handlebars, the filler caps (XL70), loosen the two or three triple clamp pinch-bolts, and remove the steering stem nut. Tap the underside of the triple clamp upward to remove it.

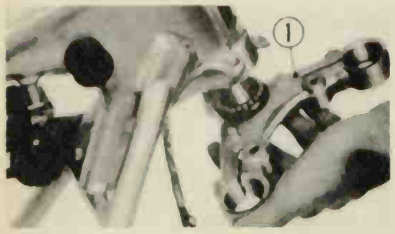
Steering head bearing adjusting nut (1)

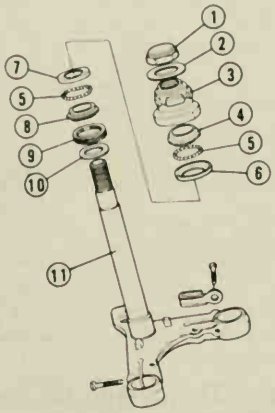
7. Tighten or loosen the adjusting nut a little at a time until the steering stem adjustment conforms to that outlined above.
8. If proper adjustment is not possible, the bearings and races will probably need to be replaced.



REMOVAL

1. Remove the front wheel, front forks, fuel tank, and handlebars.
2. Disconnect the speedometer and tachometer cables from the instruments. Remove the headlight lens and disconnect the wire harness. Remove the two bolts which secure the headlight mounting bracket and remove the tachometer, speedometer, headlight, and the headlight bracket by pulling the bracket up.
3. Remove the front fender from the steering stem by removing the four bolts (XL350/250) or three bolts (other models) securing the fender to the steering stem. Pull the fuel tank breather tube out of the triple clamp.
4. Loosen the upper triple clamp pinch-bolts (3). Remove the steering stem nut and washer. Tap the triple clamp upward with a plastic mallet to remove it.

Steering stem nut (1); rear triple clamp pinch-bolt (2)



5. Loosen the steering stem bearing adjuster nut with a pin wrench, then hold the steering stem up while unscrewing the adjuster nut the rest of the way off. Remove the steering stem top cone race and the balls from the top race.
6. Carefully pull the steering stem out from the bottom. Some of the ball bear-

ings from the lower race will most likely fall out at this time so be prepared for this. Remove the rest of the balls from the lower race when the stem is removed.

7. Remove the bottom cone race, dust seal, and dust seal washer from the steering stem if they are to be replaced. If the steering stem has been damaged and is to be replaced, the upper and lower races and balls should also be replaced.

7. Lower frome race
8. Lower cone race
9. Dust seal
10. Washer
11. Steering stem/lower triple clamp

NOTE: *A chisel is usually necessary to remove the lower cone race from the steering stem.*

8. The bearing races in the frame are a press-fit and should not be removed unless replacement is necessary. Inspect them first. If replacement is necessary, the old races can be removed by reaching through the frame lug with a suitable punch and tapping the races out from the inside of the lug.

New races are installed using a suitable sized bushing driver: i.e., one which will drive the race squarely into its seat. Be certain that the race goes straight in. These races can also be installed using a block of hard wood, of sufficient size to cover the race, in place of a bushing driver.

INSTALLATION

1. Install the dust seal washer, dust seal, and bottom cone race onto the steering stem. Use a good grade of bearing grease to coat the bottom cone race and the top race in the frame lug.

2. Embed the balls into the grease of the top frame race and the bottom cone race. Place a coat of grease on the two remaining races.

3. When the balls are in place, slip the steering stem through the frame lug and hold it in place, while refitting the top cone race and threading on the adjuster nut.

4. Tighten the adjuster nut, and move the steering stem back-and-forth to work the grease into the bearings, then back off the adjuster nut until the steering stem turns with ease, but has no play.

5. Install the upper triple clamp and fork tubes. Check that the stem moves freely of its own weight from 5°–10° off center; if not check:

a. Steering bearings too tight;
b. Bent steering stem;
c. Worn races or balls.

6. Install the flat washer, and steering stem nut.

7. Install the front wheel, front fender, headlight bracket, handlebars, and fuel tank.

Rear Shocks

No service to the rear shocks is possible. In the event of oil leaks, bent or broken plunger shaft, dented or otherwise damaged case, the shock absorber must be replaced.

If the shock absorbers are somewhat old, and one fails in the course of normal usage (such as an oil leak) it would be wise to replace both shocks to ensure equal damping characteristics.

To check a shock which is removed from the machine, place the bottom end on the ground and use the weight of your body to compress it as much as possible. Release the shock and note its rebound behavior. If the shock returns quickly at first, then slowly returns to its normal length, it is serviceable. If it returns to its normal length all at once, it should be replaced.

CAUTION: *Do not attempt to disassemble rear shock absorbers.*

Swing Arm

ALL MODELS

Inspection

1. Disconnect the drive chain. Remove the rear wheel.

2. Remove the shock absorbers and chain guard.

3. Measure the distance between the top and bottom shock absorber mounts on both sides. The two measurements must be identical, or the swing arm will have to be replaced.

4. Check that the rear wheel mounting plates are parallel.

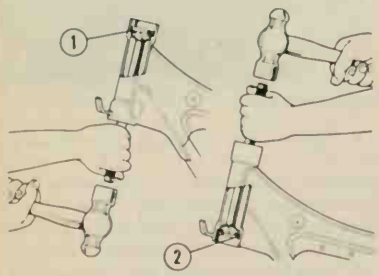
5. Grasp the legs of the swing arm and attempt to move it from side-to-side. Any noticeable side-play will indicate that the swing arm bushings need replacement.

The swing arm is most likely to be damaged if the machine is operated for any length of time with a broken or otherwise defective shock absorber.

Removal and Installation

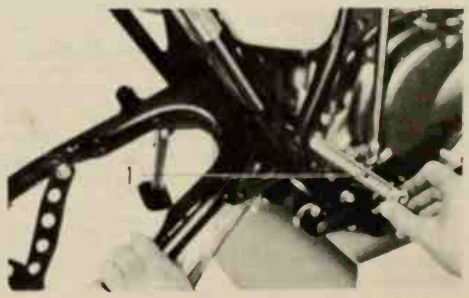
1. Proceed as above. On XL100 models, remove the left crankcase rear cover. Then remove the swing arm pivot bolt nut, and pull the pivot bolt out from the right-side.

2. Remove the swing arm by pulling it straight back.



3. The swing arm should be inspected for cracks or fractures, especially around the welds.

After removal of the swing arm, the dust seals, and bushings can be replaced. This should be done every 10,000 miles, or more often depending on how the machine is used, or if the bushings are worn (see "Inspection").



4. Remove the bushing(s), tapping them out with a hammer and punch. Once the bushings are removed, they should be replaced.

5. Lubricate new bushings with a good chassis grease. Press the bushings into the swing arm, then install the swing arm collar if fitted.

6. Install the swing arm on the machine. After tightening the swing arm pivot shaft nut, move the swing arm up and down to ensure that movement is smooth and effortless.

Maintenance

NOTE: *Common maintenance procedures are explained in detail in "General Information."*

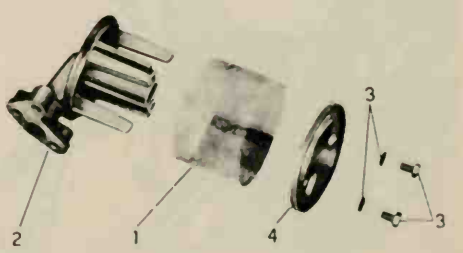
Lubrication

ENGINE

Checking

A dipstick is incorporated into the crankcase filler plug and has maximum and minimum marks on it. When checking the oil level, the engine should be warm. The filler plug must be screwed one turn into its threads to make the level reading on all models except the 850T/T3, where it should be fully threaded in. Maintain the oil level at the top dipstick mark.

Changing



1. The oil should be changed every 1800 miles under normal conditions.
2. Use SAE 10W–50 or 20W–50 oil, service rating "SE".
3. The oil should be changed when the engine is at operating temperature. Remove the drain plug at the rear of the oil pan to drain off the oil. After draining is complete, add the correct amount of oil for your machine (refer to the "Maintenance Data" chart). Run the engine for a minute, then recheck the level. Top up if necessary.

OIL FILTER

All Models Except 850T/T3

A wire mesh oil filter screen is fitted around the oil pump intake. The screen should be removed for cleaning about every 15000 miles.

1. Drain the oil.

Oil filter screen assembly: 1, screen; 2, housing; 3, bolts and washers; 4, cover

2. Remove the oil pan bolts. If the pan will not come free, tap around the sides with a plastic mallet. Do not attempt to pry the pan off.

3. Remove the two filter cover bolts, and take away the filter screen. Clean it in a solvent and dry thoroughly.

4. Installation is the reverse of removal. Use a new pan gasket.

Tighten the pan bolts gradually and evenly.

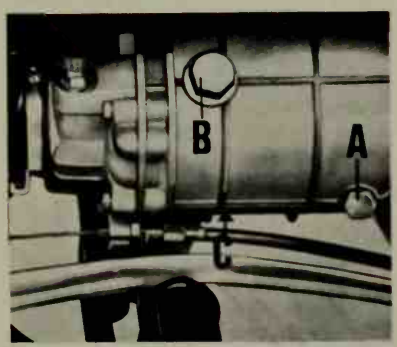
850T/T3

Most 850T and all T3 models have an oil filter screen and a replaceable cartridge oil filter, both of which are fitted to the oil pan. Cleaning of the filter screen and replacement of the cartridge filter are necessary about every 15,000 miles.

1. Drain the oil.

2. Remove the oil pan bolts. If the pan resists removal, tap around the sides with a plastic mallet. Do not attempt to pry the pan off.

3. Remove the filter screen, clean it in a solvent and dry thoroughly before installation.



4. Unscrew and remove the filter cartridge and replace it with a new unit.

5. Installation is the reverse of removal. Use a new pan gasket. Tighten the pan bolts gradually and evenly.

TRANSMISSION

Checking

1. A level plug is fitted to the right side of the transmission housing to enable the level to be checked periodically. This should be done every 1800 miles.

Transmission oil level plug (A), filler (B), and drain plug (C)

2. Check when the engine is at operating temperature. When the plug is removed, the oil should just begin to seep out of the plug hole.

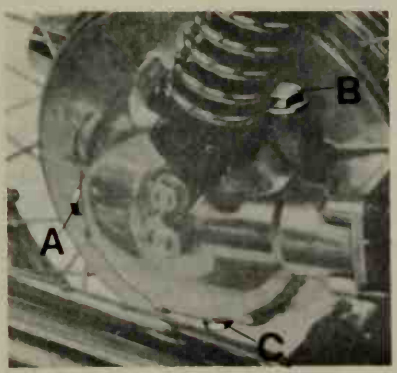
3. Top up, if necessary, by adding oil through the filler plug hole until oil just begins to seep out of the level plug hole.

Changing

1. The transmission oil should be changed every 6,000 miles. SAE 90 EP gear oil is recommended.

2. Change the oil when the engine is at operating temperature. Carefully remove the drain plug at the very bottom of the transmission and allow the old oil to drain for several minutes. When fitting the drain plug, be very careful not to overtighten it. It is easy to strip the threads.

3. Add 1¾ pints (0.75 l) of SAE 90 oil through the filler plug. After allowing the oil to settle for a moment, check the level. Top up if necessary.



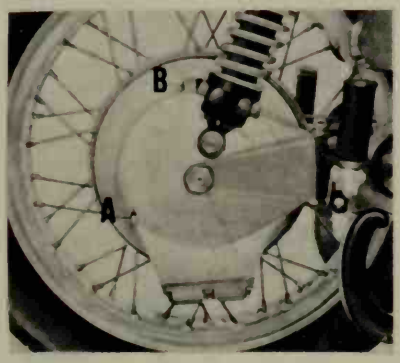
DRIVE BOX

Checking

1. A level plug is provided to check the drive box oil, which should be done every 1,800 miles. When the plug is removed, the oil should just begin to seep out.

The oil should be checked when the engine is warm.

When removing or installing the level plug, it is important to do this carefully. It is very easy to strip the threads in the drive box.



Drive box level plug (A), filler (B) and drain plug (C) (early)

Changing

1. Drive box oil should be changed every 6,000 miles. Change the oil when the unit is at operating temperature.

2. On early models, a drain plug is provided. Sport and 850s have a cover plate secured by allen screws. After removing the screws, tap the sides of the cover to break it free.

Drive box level plug (A) and filler (B). Remove cover plate at bottom to drain oil (later models)

3. After refitting the cover or drain plug, add the correct amount of SAE 90 EP oil through the filler plug. Refer to the "Maintenance Data" chart.

4. After allowing the oil to settle for a moment, check the level and top up if necessary.

FRONT FORKS

1. The front fork oil should be changed every 12,000 miles, or every year, whichever comes first.

2. V7, V750, and V850 models use standard hydraulically damped forks, while Sport and 850T/T3 models utilize forks in which the dampers are sealed units (much like rear shocks). The oil added to this type of fork is used only to lubricate the internal components, and does not affect damping characteristics.

3. ATF can be used in all forks, although any quality oil designed for motorcycle forks is also acceptable.

4. Drain one fork leg at a time. Remove the drain plug at the bottom of the fork slider. Pump the forks up and down several times to expell all of the old oil. Refit the drain plugs.

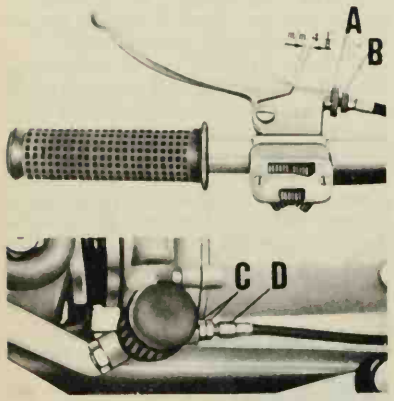
5. On Sport and 850T/T3 models, place a support beneath the crankcase to prevent the forks from collapsing when the filler caps are removed. Remove the bolts which secure the instrument bracket to the forks.

Fork drain plug (A) and filler cap (B) (Sport shown)

6. Remove the filler cap from each fork leg. Add the correct quantity of fork oil for your model as given in the "Maintenance Data" chart.

NOTE: *Slight leakage at the fork seals on Sport and 850T/T3 models may be due to an excess of oil in the fork, and is no cause for concern. Since the fork dampers are sealed, the leakage of lubricating oil will not affect fork operation.*

CHASSIS LUBRICATION



1. The steering head and wheel bearings should be lubricated with a good grade of bearing grease every 12,000 miles.

2. The swing arm pivot bearings should be packed with bearing grease whenever the swing arm is removed.

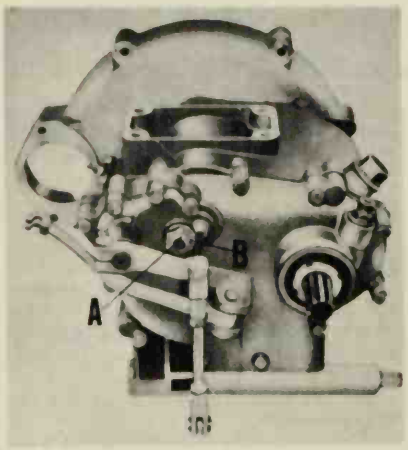
Service Checks and Adjustments

CLUTCH

1. Maintain clutch cable adjustment so that the clutch handlebar lever can be moved ⅛ in. (4 mm) before the clutch begins to disengage. This distance is measured between the clutch lever and lever bracket as illustrated, and can be made either with the cable adjuster on the handlebar, or with that on the transmission.

Clutch adjustment can be made with either the handlebar adjuster (A,B) or the lower cable adjuster (C,D)

2. If adjustment of the cable to the proper specification does not result in good clutch operation, check the adjustment of the clutch pushrod adjuster on the rear of the transmission, which is fitted to 850 and 750 Sport models.



The pushrod is adjusted by means of a screw and locknut on the clutch operating lever.

3. To check this adjustment, run the clutch cable adjusters in until there is maximum freeplay. Measure the distance between the center of the cable fitting in the lever and the transmission rear cover. This distance should be 67–69 mm for Eldorado models; and for Sport and 850T/T3 models: 65 mm for machines with disc or rod-operated rear brakes; 75 mm for machines with cable-operated rear brakes. To make the adjustment, loosen the locknut and turn the screw until the distance is correct. Next, adjust the clutch cable as described in Step 1.

SHIFTER MECHANISM

If noisy and difficult gear shifts are encountered, and the clutch has been adjusted properly, they may be remedied by adjusting the shift mechanism. This is located at the rear of the transmission.

To adjust, loosen the locknut and turn the adjusting screw (V700, V750) or eccentric nut (850s and 750 Sport) in or out until a position is arrived at where the gears will shift smoothly both up and down and where neutral can readily be found. Then hold the screw or eccentric nut in position and tighten the locknut.

Shifter adjuster: adjusting screw (A), locknut (B) (V700, V750)

BRAKES

Disc Brake

1. A periodic check of the master cylinder fluid level and pad wear is the only routine maintenance required. The fluid level should not be allowed to drop more than 8 mm (0.3 in.) below the maximum mark inscribed inside the master cylinder. The level will drop somewhat as the pads wear, but when this point is reached, fresh fluid should be added.

Never use brake fluid from an unsealed container.

Take precautions to ensure that the fluid does not contact painted surfaces.

Use DOT 3 hydraulic brake fluid.

2. The brake system should be flushed and refilled with fresh fluid at least once a year. Refer to "Chassis" for procedures.

3. If brake operation is not satisfactory, or if the lever feels mushy, the system should be bled. Refer to "Chassis" for procedures.

4. A clearance of 0.05–0.15 mm (0.002–0.006 in.) must be maintained between the lever end and the piston. The adjustment can be effected with the screw on the lever bracket. This adjustment is usually not necessary unless the master cylinder has been disassembled.

5. About every 3,000 miles, the pads should be checked for wear. To remove the pads: remove the dust cover, remove the tapered pin and spring, remove the retainer pins, and take out the pads. Both pads must be at least 6 mm (0.2 in.) thick. If either is less than this amount, replace them as a set.

New pad thickness is 9 mm (0.35 in.).

Installation is the reverse of removal. Note that fitting new pads may result in a rise of the master cylinder fluid level. Drain off any excess fluid by means of the bleed screw on the caliper if the level is above the maximum mark. Hold the brake on, loosen the bleed screw (fluid will flow out and the lever will be pulled to the handgrip). Tighten the screw before releasing the lever.

NOTE: *Avoid hard application of the brake for at least fifty miles after fitting new pads.*

6. It will not be necessary to bleed the brake lines after fitting new pads. Operate the brake lever several times to position the pads before riding.

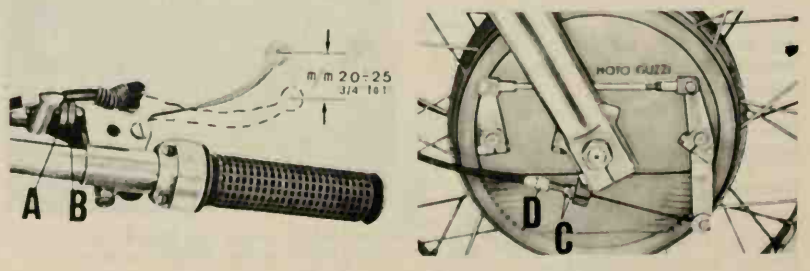
Front Drum Brake

Twin-Leading Shoe

1. A twin-leading shoe type brake is fitted to all models with a front drum brake with the exception of the V7 Sport.

2. The brake adjustment is correct if the brake lever on the handlebar can be moved 20–25 mm (¾–1 in.) before the shoes contact the drum. This distance is measured at the tip of the lever.

3. If adjustment is necessary, use the cable adjuster at the brake plate so that the proper amount of lever movement is obtained. For fine adjustments, use the adjuster at the handlebar.



Four-Leading Shoe

1. The V7 Sport front drum brake is a four-leading shoe type. Two independent cables are used, along with a common adjuster at the handlebar which allows both cables to be adjusted simultaneously.

2. The brake lever at the handlebar should have 20–25 mm (¾–1 in.) of free movement before the shoes contact the drum. This is measured at the tip of the lever. For minor adjustments, use the handlebar adjuster to obtain the proper freeplay.

3. If the handlebar adjustment has been used up, or if brake operation is not satisfactory, proceed as follows:

4. Run the handlebar adjuster all the way in. Disconnect the right side brake cable from the lever at the brake plate. Use the cable adjuster on the brake plate for the left side brake cable to give 20–25 mm (¾–1 in.) of movement at the handle-

Front drum brake adjustment. Make minor adjustments with the handlebar adjuster (A,B), major adjustments with that on the brake plate (C,D). On Sport models be sure to adjust both brake plates when using the lower brake plate adjuster

bar lever before the left side shoes contact the drum.

5. Reconnect the right side brake cable. Apply the handlebar lever, ensuring that it is still adjusted to the proper amount of movement. Check that the right side brakes are contacting the drum by pushing on the brake plate lever with your thumb. If this lever can be moved with the brake applied, it indicates that there is too much slack in the right cable. Use the adjuster at the brake plate to take up slack until the right side shoes are in contact with the drum.

6. Apply the brakes, and check for movement of the brake plate levers on both sides by pushing on them. If both sides are in contact with the drum, no movement will be possible.

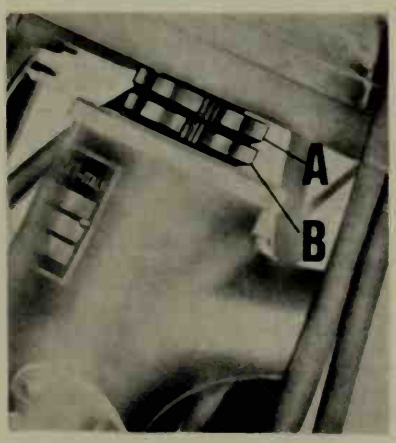
7. Make final adjustments of handlebar lever movement with the adjuster at the handlebar.

Rear Drum Brake

1. The rear brake may be either cable or rod-operated. A twin-leading shoe unit is used on late models.

The brake should be adjusted so that the brake pedal can be moved 20–25 mm (¾–1 in.) before the shoes contact the drum. On rod-operated brakes, this adjustment should be checked with the machine off the stand, and a rider in place on it.

2. Rod-operated brakes are adjusted by means of the thumb screw at the end of the rod.



Cable-operated brakes are adjusted by means of locknuts on the cable adjuster.

STEERING HEAD

1. A periodic check should be made of the steering head bearings. With the front wheel supported off the ground, the forks should swing easily from lock to lock. If the forks are tight or if movement is noisy, the bearings should be adjusted. Also check for excessive play by grasping the fork sliders and pushing and pulling on them. No play should be noticeable.

2. On V700, V750, and V850 models, two locknuts beneath the upper triple clamp are used to adjust the bearings. Loosen the uppermost nut, and turn the lower so that bearing action conforms to the standards in Step 1. Then tighten the upper nut against the lower while holding the lower in place.

3. On Sport and 850T models, adjustment is accomplished by loosening the rearmost upper triple clamp pinch bolt, loosening the nut beneath the steering damper knob, and using the adjusting nut beneath the triple clamp to make the fork movement conform to those standards outlined in Step 1.

Steering head bearing adjusting nuts (A,B) (early models shown)

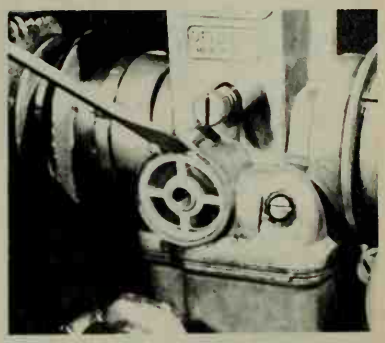
FUEL SYSTEM

Air Cleaner

Models fitted with an air cleaner use a paper element type. When the filter becomes dirty it may be possible to prolong its service life by blowing deposits off with compressed air. It is preferable, however, to simply replace the element.

The element should be checked about every 6,000 miles under normal conditions.

To remove the air filter on the T3:



1. Lift the seat, supporting it by its rod.
2. Remove the tool box.
3. Remove the gas tank.
4. Disconnect the wiring from the battery (negative first) and unbolt the brackets.
5. Unhook the springs and remove the rubber oil breather manifold.
6. Remove the nut securing the oil breather to the housing, disconnect the lines and take out the oil breather.
7. Remove the air filter.
8. Installation is the reverse of the removal procedure.

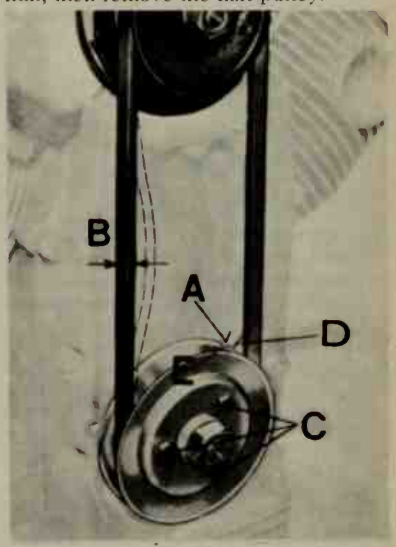
Fuel Filters

1. Mesh filter screens are fitted to the fuel petcocks and each carburetor. These filters should be serviced every 6,000 miles.

2. The petcock filters are reached by removing and draining the gas tank. Unscrew and remove the petcocks. Clean the filters in a solvent and blow dry. Replace them if punctured or damaged.

3. The carburetor fuel filters are located beneath the feed banjos on the carburetor bodies. After removing the banjo securing screw, lift off the banjo and remove the filter screen. Clean in solvent. Replace them if punctured or damaged.

Removing the carburetor fuel filter screen



GENERATOR BELT

On models fitted with a DC generator, a v-belt is used to drive the unit.

Normal belt slack (A) is about 1 cm per 10 kgs (0.39 in./21 lbs). Avoid overtightening the belt as this may cause premature wear to the belt and generator assemblies.

Adjust the generator belt in the following manner:

1. Remove the three bolts (B) which secure the outer half-pulley to the pulley hub, then remove the half-pulley.

Generator belt tension (A)

2. Add or remove spacing collars as necessary. Removing spacers will increase belt tension and installing spacers will decrease it. Spacers should be removed or installed one at a time and, if more than one spacer is removed, the extras should be placed at the front and rear of the pulley so as not to throw the pulleys out of alignment.

3. Replace the outer half-pulley and secure the three mounting bolts. Recheck the adjustment and repeat the operation until a satisfactory adjustment is attained.

GENERATOR

Every 6,000 miles the generator commutator should be cleaned with a clean cloth slightly moistened with gasoline.

If carbon or copper dust has settled in the mica insulators, it should be blown clean with compressed air.

At this time inspect the brushes and replace them if chipped or excessively worn. Be sure the brushes make perfect contact with the commutator.

Tune-Up

NOTE: *Common tune-up procedures are explained in detail in "General Information."*

Valve Adjustment

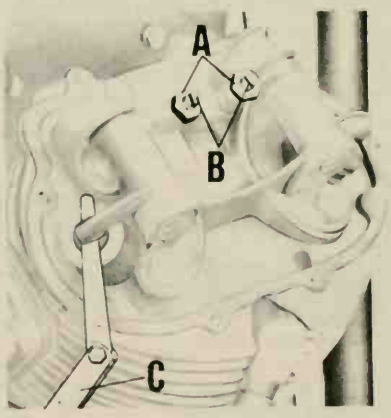
NOTE: *Valves must be adjusted when the engine is cold.*

V700, V750, V850

1. Remove the valve covers. Remove the spark plugs.

2. Place the transmission in gear, and rotate the rear wheel to turn the engine over in the following manner.

3. Beginning with either cylinder, turn the rear wheel in the normal direction until the intake valve for that cylinder opens and just begins to close.



4. Using a flexible swizzle stick or similar non-rigid object, insert it carefully into the spark plug hole until it touches the piston crown.

5. Continue turning the rear wheel slowly. The piston should rise. When the piston reaches the highest point of its travel, stop. The piston should now be at TDC (top dead center) and on the compression stroke. Turn the wheel a few degrees in either direction to verify that the piston is at the top of its stroke. Check that there is clearance at both valves. If there is not, the piston is at the top of the *exhaust* stroke, and the engine must be turned 360° to obtain the compression stroke.

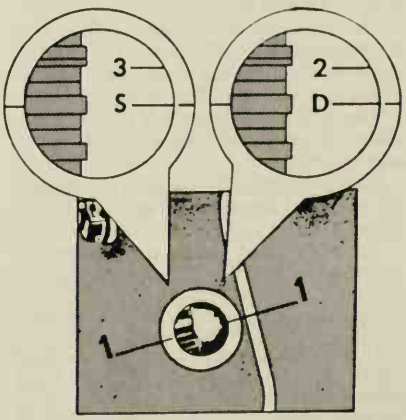
6. When the piston is at TDC on the compression stroke, the valves can be adjusted. Correct clearance is 0.15 mm (0.0059 in.) for the intake valve, and 0.25 mm (0.0098 in.) for the exhaust valve.

The measurement is made between the valve stem and the rocker arm.

7. If adjustment is necessary, loosen the locknut and turn the adjusting screw in or out until the feeler gauge is a drag fit. Tighten the locknut while holding the adjusting screw in place. Recheck the adjustment after tightening the locknut.

Valve adjustment is made with the screws (B) after loosening locknuts (A)

8. Repeat the procedure for the remaining cylinder, turning the engine over to position that piston at TDC on the compression stroke.



9. Before installing the valve cover screws, coat the threads with oil or an anti-seize compound to facilitate future removal. Tighten the screws gradually and in a cross pattern.

750 SPORT/S, 850T/T3

These models have timing marks on the flywheel, making it easy to position the piston at top dead center for valve adjustment.

1. Remove the spark plugs. Remove the valve covers. Remove the rubber cap from the inspection hole on the right side of the crankcase.

2. The flywheel has several marks among which are "S" and "D". "S" indicates that the left cylinder is at TDC and "D" that the right cylinder is at TDC when the letters are aligned with the slash mark on the side of the inspection hole.

TDC for the left cylinder occurs when flywheel mark "S" aligns with timing mark "1." "D" is TDC for the right cylinder. Nos. "2" and "3" are fixed advance firing points.

3. Engage the transmission. Using the rear wheel, turn the engine over until either of these marks appears through the inspection hole, then line up the letter with the mark on the hole. Check for clearance at both valves for that cylinder (i.e. if the "S" mark is aligned, check the left cylinder).

If there is clearance at both valves, the piston is at TDC on the compression stroke and the valves for that cylinder can be adjusted. If there is not clearance at both valves, the piston is at TDC on the exhaust stroke, and the engine must be turned 360° to get it on the compression stroke.

4. Correct clearance for both intake and exhaust valves is 0.22 mm (0.0089 in.). The measurement is made between the valve stem and the rocker arm.

5. If adjustment is necessary, loosen the locknut and turn the adjusting screw until the clearance is correct. Hold the adjusting screw in place while tightening the nut. Recheck the adjustment afterwards.

6. Turn the engine over so that the remaining cylinder is at TDC on the compression stroke and repeat the procedure.

7. Before installing the valve cover screws, coat the threads with oil or an anti-seize compound to facilitate future removal. Tighten the screws gradually and in a cross pattern.

Contact Breaker Points

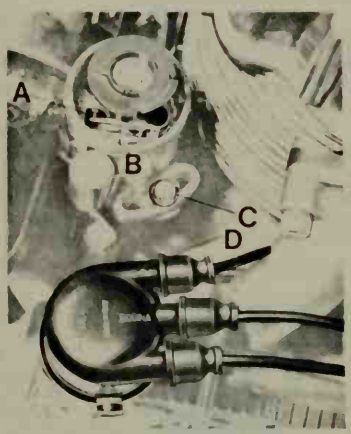
LOCATION

1. The points are located beneath a cap just inside the right cylinder.

2. 750 Sport and 850T/T3 models use dual points, while other models have a single point set with a rotor and distributor cap.

GAPPING

Points should be filed (if necessary) and cleaned before gapping.



V700, V750, V850

A single set of points is used, which simplifies the gapping procedure.

1. Remove the distributor cap. Remove the spark plugs. Engage the transmission, and use the rear wheel to turn the engine over until the points are open to their maximum gap.

2. Check the point gap with a feeler gauge. Proper gap is 0.42–0.48 mm (0.016–0.018 in.).

3. If the gap is not correct, loosen the points securing screw just enough to enable the fixed point to be moved.

Point gap adjustment (A) is made after loosening screw (B). Bolt (C) is for ignition timing adjustment. Plug lead #2 from distributor cap (D) is for the left cylinder.

Adjust the gap with a thin screwdriver applied at the pry point. Tighten the screw and recheck the gap.

750 Sport, 850T/T3

These models utilize two sets of breaker points. Each set is gapped separately.

1. Remove the points cap. Remove the spark plugs. Engage the transmission, and use the rear wheel to turn the engine over until one of the sets of points is open to the maximum gap.

2. Check the gap with a feeler gauge. Proper clearance is 0.37–0.43 mm (0.014–0.017 in.) for the Sport and T3, and 0.42–0.48 mm (0.016–0.018 in.) for the 850T.

3. If the gap is not correct, loosen the two screws which secure the points (see illustration) just enough to enable the fixed point to be moved. Adjust the gap with a thin screwdriver applied at the notch provided. Tighten the screws and recheck the point gap.

To adjust point gap, loosen the screws (arrows) for each point set. Loosening the wrong screws for the lower point set will necessitate resetting the ignition timing

4. Turn the engine over until the other points set is open, and repeat the procedure.

LUBRICATION

When the points are gapped, a few drops of clean motor oil should be applied to the lubricating felt.

Care should be taken not to overlubricate the felt, since this may cause fouling of the points.

Ignition Timing

On DC generator models, the generator drive pulley on the crankshaft is fitted with several marks which indicate piston position when aligned with a stationary mark on the crankcase.

On alternator models, the timing marks are on the crankshaft flywheel and are visible when the rubber cap on the side of the crankcase is removed.

NOTE: *Points must be cleaned and gapped before checking the timing. Dirty points will cause inaccurate readings.*

GENERATOR MODELS

The generator drive pulley has four timing marks on the inner lip which are used to set the ignition timing. Beginning with the first of these, and proceeding *clockwise* these marks represent: the top dead center position for the left cylinder (B), the fixed advance firing point (C), the automatic advance firing point (D), and, finally, the total advance firing point (E). There is, in addition, a stationary timing mark on the crankcase.

NOTE: *The crankshaft rotates clockwise when viewed from the front.*

Generator models timing marks

Spark plug leads are numbered "1" and "2" for the right and left cylinders respectively.

Dynamic Timing

1. Remove the generator belt cover. Hook the strobe light up to the left cylinder, and, illuminating the timing marks, run the engine. At the following rpm, the pulley marks should align with the stationary mark in this manner:
   a. Mark "C" at 1200 ± 100 rpm
   b. Mark "D" at 2200 ± 100 rpm
   c. Mark "E" at 3600 ± 100 rpm

2. If the marks do not line up with the stationary mark at the proper engine speed, loosen the distributor shaft lock bolt, and rotate the distributor a few degrees in the direction necessary so that alignment is achieved. In most cases it will not be necessary to turn the distributor more than a few degrees. Tighten the lock bolt and recheck the timing.

3. If it is not possible to get the "E" (full advance mark) aligned, either the automatic advance unit is not working correctly, or the breaker points are worn to the point of replacement.

Static Timing

1. Remove the generator belt cover. Remove the distributor cap. Hook up the continuity light or test light so that one lead is connected to ground, and the other to the primary wire terminal or moveable point.

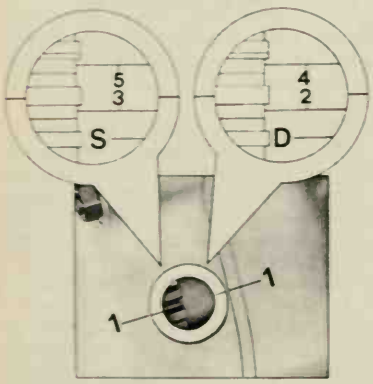
2. Turn the engine over slowly until the contact on the distributor rotor approaches the vicinity of the distributor *cap* contact for the left cylinder (which is marked "2" on the distributor cap). The engine should be turned in the normal running direction—the generator drive pulley will rotate clockwise when viewed from the front of the engine.

3. Continue to rotate the engine slowly. The test light should react at the moment the mark "C" on the pulley aligns with the stationary timing mark.

4. If the test light does not indicate that the points have opened when the "C" mark and the stationary mark are aligned, loosen the distributor shaft lock bolt and rotate the distributor a few degrees in the direction required so that

alignment is achieved. Tighten the lock bolt and recheck the timing.

ALTERNATOR MODELS



Timing marks are provided on the flywheel to set the ignition timing. Because of the dual-point ignition, timing must be checked for both cylinders.

NOTE: *Crankshaft rotation is clockwise when viewed from the front.*

The breaker points which are connected to the *red* primary wire are the points for the *right* cylinder; the points with the *green* primary wire are for the *left* cylinder.

Each cylinder also has three timing marks on the flywheel and these are as follows (refer to the illustration):

"S" and "D": "S" is the top dead center position for the left cylinder; "D" is TDC for the right cylinder.

Alternator models flywheel timing marks

"2" and "3": these marks indicate the fixed advance firing points for the right and left cylinders respectively. They indicate piston positions of 13° before TDC for the Sport, or 8° before TDC (850T) or 2° before TDC (T3): that is, the firing point before the automatic advance mechanism comes into effect.

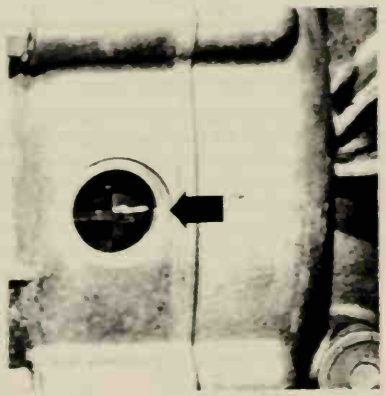
"4" and "5": these are the full advance firing points for the right and left cylinders respectively. They indicate piston positions of 39° BTDC (Sport), 34° BTDC (850T) or 33° BTDC (T3): that is, the full advance firing point.

Dynamic Timing

The right cylinder *must* be timed first.

1. Remove the inspection cap from the crankcase so that the timing marks on the flywheel are visible. Remove the points cap. Clean and gap the points.
2. Hook up the strobe light according the manufacturer's instructions to time the right cylinder.

All of the following rpm values are plus or minus 200 rpm.



3. Start the engine, aiming the strobe light at the flywheel marks. The mark indicated as "2" in the illustration must align with the mark on the side of the inspection hole at rpm up to 1000 (T3) or 1500 (other models). At 6,000 rpm (T3) or 4,400 rpm (other models) and above, the mark indicated as "4" must align with the mark on the side of the inspection hole.
4. If the marks do not align at the given rpm, loosen the two round head screws which secure the points plate to the housing, and rotate the entire plate a few degrees in the direction necessary to bring the marks into alignment. Tighten the screws and recheck the timing.
5. Having timed the right cylinder, the remaining cylinder must be checked as well. Proceeding as before, the mark "3" must align with the inspection hole mark at 1,500 rpm, (T3:1,000 rpm) while the mark "5" must align at 4,400 rpm (T3: 6,000 rpm).
6. If adjustment is necessary, loosen the two hex-head screws which secure the left cylinder's breaker points to the points plate and move the points with a thin screwdriver at the pry point provided so that the marks can be brought into alignment.

It will be noted that adjusting the timing for the right cylinder will affect both cylinders, while the left cylinder is adjusted independently.

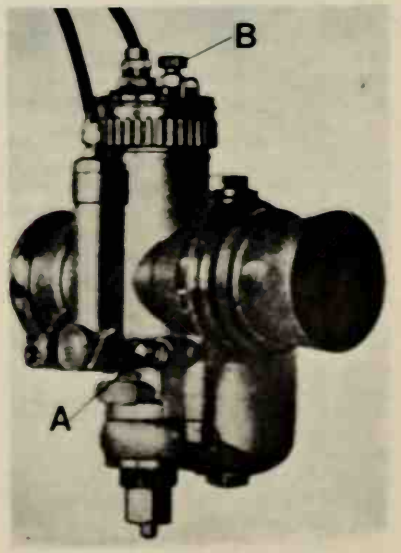
Static Timing

The right cylinder *must* be timed first.

1. Remove the inspection cap from the crankcase so that the timing marks on the flywheel are visible. Remove the spark plugs. Remove the right cylinder valve cover. Remove the points cap. Clean and gap the points.
2. Hook up the test light to the points for the right cylinder (red lead).
3. Engage the transmission and use the rear wheel to turn the engine over in the normal running direction until the right cylinder's intake valve open and begins to close. Continue turning the engine over, slowly, until the "D" mark on the flywheel aligns with the mark on the inspection hole. The right cylinder is now at TDC on the compression stroke.

Right cylinder TDC mark (D)

4. Turn the engine backwards until the fixed advance timing mark ("2" in the illustration) comes into view and passes the inspection hole timing mark.
5. Turn the engine in the normal direction of rotation once more. As the "2" mark aligns with the inspection hole mark, the points should open as indicated by the reaction of the test light.
6. If this is not the case, loosen the two round head screws which secure the points plate and rotate the entire plate in the necessary direction so that the points begin to open as these marks align. Tighten the screws and recheck the timing.
7. The left cylinder must now be set. Turn the engine over in the normal direction of rotation until the "S" mark (left cylinder at TDC) is aligned with the inspection hole mark. Now repeat the timing procedure outlined above to see if the points open when the mark "3" aligns with the inspection hole mark. If they do not, loosen the two screws which secure the left cylinder's points to the plate, and position them so that they open when the marks align. Tighten the screws and recheck the timing.



It will be noted that adjusting the timing for the right cylinder will affect timing for both cylinders, while the left cylinder is adjusted independent of the other.

Carburetors

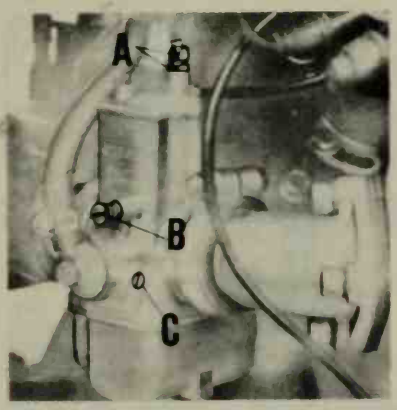
Three adjustments to be made to the carburetors are the idle mixture, idle speed, and synchronization.

Carburetor adjustments must be made when the engine is at operating temperature, preferably after all of the other tune-up operations outlined have been carried out.

1. Ensure that the throttle cables have enough freeplay so that the throttle slides are closing fully.
2. Turn the pilot screws in very carefully until they bottom lightly, then back them out the proper number of turns for your model (refer to the "Tune-Up Specifications" chart).
3. Start the engine (which should already be at operating temperature). With the engine idling at 1000–1200 rpm (T3:900–1000 rpm), disconnect one of the spark plug leads, and turn the pilot screw for the running cylinder in or out so that the cylinder is running at the highest

Pilot screw (A) and throttle stop screw (B)

speed. It should not be necessary to alter the adjustment more than ½ turn from the given setting. If it is necessary, suspect a dirty idle passage or damage to the pilot screw's tapered tip.



4. Connect the spark plug lead, rev the engine a few times to clean it out, then disconnect the other lead, and repeat the procedure with the other cylinder.

5. When both pilot screws have been adjusted in this manner, connect both leads, rev the engine a few times, and set the idle speed in this manner:

6. When either spark plug lead is disconnected, the other cylinder should fire 4–5 times before stalling.

Adjust the throttle stop screws so that this condition is met.

7. When both plug leads are connected, idle speed should be 1000–1200 rpm (T3:900–1000 rpm). If this is not the case, turn both throttle stop screws by equal amounts until the desired idle speed is obtained.

Cable adjuster (A), throttle stop screw (B), pilot screw (C)

8. To synchronize the throttle slides, first remove the air cleaner assembly (if fitted), the rubber sleeves, and the velocity stacks (if fitted), so that the carburetor intakes are readily accessible.

9. Place a finger in each carburetor bore and check that both slides begin to rise at exactly the same time when the twist grip is turned.

An alternative method is to turn the twist grip until one of the slides just clears the carburetor bore and check that the other is in the very same position.

10. If an adjustment is necessary, turn the throttle cable adjusters on the carburetor caps in or out until the slides are sychronized.

Engine and Transmission

NOTE: *For engine component inspection procedures, refer to "Engine Rebuilding" under General Information.*

Engine Removal and Installation

Due to the weight of the engine-transmission assembly, engine removal should not be undertaken by less than two people. Cleaning the unit thoroughly before removal is recommended.

V700, V750, V850

1. Run the engine until its normal operating temperature is reached, then drain the oil. Drain the transmission oil.

2. Remove the battery covers from both sides, then disconnect the battery cables.

3. Disconnect the speedometer cable from the transmission housing.

4. Remove the tank, seat, and battery, then remove the battery support plate.

5. Disconnect the throttle and choke cables at the carburetors, or remove the carburetors and position them out of the way.

6. Disconnect the clutch, starter, and neutral indicator cables from their mounting positions on the engine.

7. Disconnect and remove the ignition coil, distributor cap, spark plug leads, and the distributor rotor.

8. Remove the generator covers, generator belt guard, and the generator unit. It is not entirely necessary to remove the generator; it may be repositioned to gain sufficient clearance.

9. Remove the exhaust system.

10. Block the engine to keep it from falling out of the frame, then remove the bolts which secure the engine-transmission assembly to the frame. Remove the engine by slipping it forward, tilting it to the right, and lifting it out of the frame.

11. Installing the engine is a reversal of the removal process.

SPORT AND 850T/T3

1. Drain the engine and transmission oil.

2. Remove the gas tank. Disconnect and remove the battery. Remove the air cleaner, if fitted.

3. Unbolt and carburetors and manifolds from the cylinder heads, and remove them along with the twist grip and cables.

4. Remove the mufflers.

5. Disconnect all wiring and control cables at the engine: tach and speedometer, clutch cable, electric starter lead, solenoid wires, ignition coil high and low tension leads, etc. Remove the alternator cover. Code the wires to the terminals before disconnecting them.

6. Place a sturdy crate or a scissors jack beneath the oil pan so that it supports the engine at about the same height as the center stand.

7. Remove the rear wheel. Unbolt the rear shocks from the swing arm. Remove the disc brake caliper, if applicable. Loosen each of the chrome swing arm bushing locknuts. The bushings should be removed carefully with a screwdriver so that the locknut does not change its position on the threads.

8. Loosen the clamp on the engine

side of the drive shaft rubber boot. Pull the swing arm off the machine.

NOTE: *The drive shaft coupling splines are a very tight fit and some effort may be needed to separate them.*

9. Remove the exhaust pipe mounting clamps from the frame. Remove the gearshift linkage.

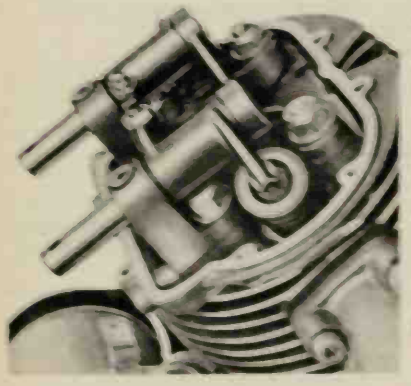
10. Unbolt the battery box from the engine. Unbolt the lower frame rails from the main frame assembly.

11. Very carefully lift up the main frame assembly complete with the front end to separate it from the engine and frame rails. The engine/transmission unit will remain in place supported by the centerstand and crate or jack.

12. Installation is the reverse of the above. Be sure all wiring connections are correct. Be sure that the frame rail bolts are very tight, and the swing arm is properly aligned when refitted.

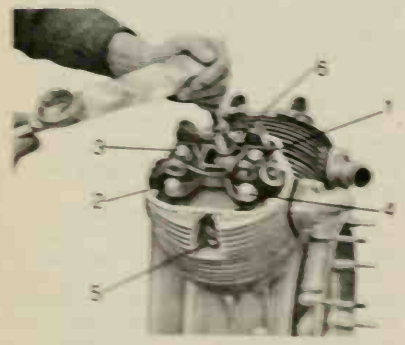
Top End

CYLINDER HEAD



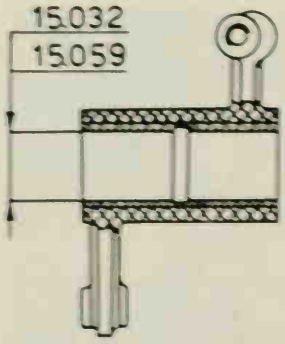
Removal

1. Remove the gas tank. Remove the exhaust pipe. Disconnect the spark plug lead. Remove the plug.

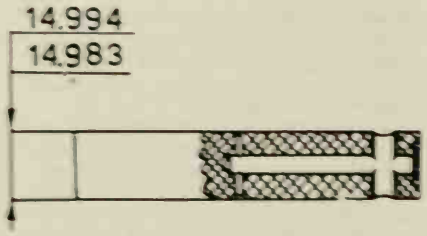


2. Unbolt the carburetor manifold from the head. Disconnect the oil feed line at the head.

3. Remove the valve cover and gasket.



4. Remove the rocker arm shaft lock bolts, and push out the rocker arm shafts.



Removing the rocker arm shafts

Cylinder head bolt tightening and loosening

Rocker arm and shaft dimensions

When the shaft is removed, lift out the rocker arms complete with the spring and thrust washer. Remove the pushrods.

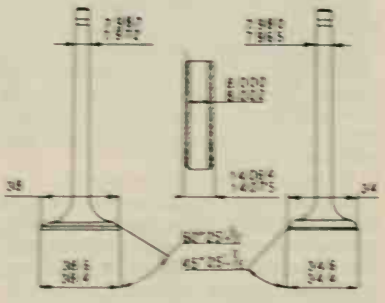
5. Loosen each cylinder head nut about ¼ turn, then remove them. Remove the rocker arm support.

6. Remove the head and the head gasket. If the head is stuck, tap carefully at the sides with a plastic mallet.

7. Remove the valves by compressing the spring(s) and taking out the keepers.

Inspection

1. Maximum allowable head warpage is 0.05mm (0.002 in.).

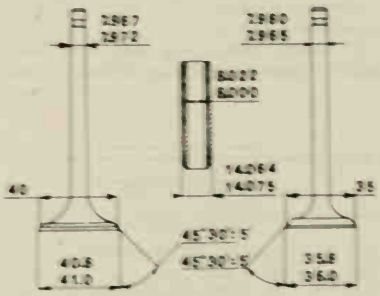


2. Rocker arm shaft-to-bore clearance must be within 0.038–0.076mm (0.0015–0.0029 in.).

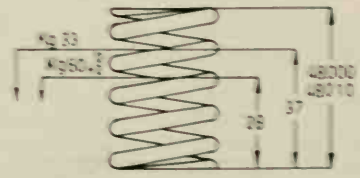
3. Valve guide-to-stem clearance should be within 0.013–0.035mm (0.0005–0.0019 in.) for the intake valves, and 0.020–0.057mm (0.0008–0.0022 in.) for the exhaust valves.

If the clearance exceeds these specifications, replace the valves or guides.

4. To replace the valve guides, heat the head to about 200° C., and drive the guides out with a suitable drift. Drive new guides in fully. New guides must be reamed to the proper size after installation. Oil the ream lightly when it encounters interference. Remove metal chips as soon as they occur, and always continue to rotate the ream when removing or installing it.



5. The valve seats and seating areas should be no less than 0.8 mm (0.032 in.) wide at the narrowest point, nor wider than 1.5 mm (0.060 in.)

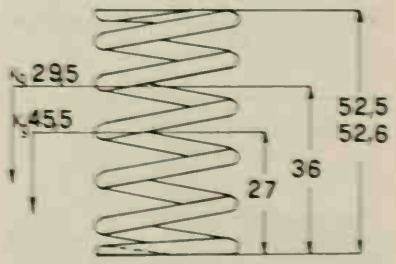


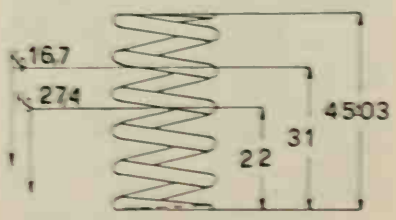
Valve and valve seat dimensions: intake (left), exhaust (right) (V700)

Seat dimensions are shown in the accompanying illustrations.

6. For other component specifications, refer to the illustrations.

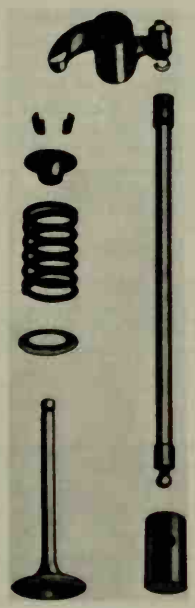
Valve and valve seat dimensions: intake (left), exhaust (right) (All except V700)





Valve spring dimensions in mm (V700)

Installation



1. Installation is the reverse of the removal procedure.

2. Use new valve keepers and a new head gasket.

Valve spring dimensions in mm (All except V700)

Valve assembly

3. When installing the cylinder head, nuts must be torqued in a cross pattern a few ft lbs at a time until the specified torque is reached. This is 29–32 ft lbs on Sport and 850T/T3 models, and 27 ft lbs on all others. The threads on the cylinder head studs should be clean and lightly oiled before installing the nuts, or incorrect torque readings may be obtained.

CYLINDER AND PISTON

Removal

1. Remove the cylinder head.
2. Rotate the piston to TDC, and lift off the cylinder until the spigot clears the crankcase. Stuff a clean lint-free rag beneath the cylinder to catch any foreign matter.
3. Continue lifting off the cylinder until it is clear of the piston.
4. To remove the piston from the rod, remove the wrist pin circlips. New ones must be used upon installation. Gently heat the piston crown (but not in excess of 60° C/140° F), and push out the wrist pin, either with a suitable drift, or the special factory tool. The wrist pin must not be struck a blow. Always push the pin out with steady pressure and while supporting the piston with a free hand. To do otherwise risks bending the connecting rod.
5. After removing a piston, mark it for its cylinder (i.e. LH or RH) and also mark the exhaust side so that the piston can be installed the correct way. Keep each wrist pin with its own piston.
6. Remove the cylinder base gasket.
7. Remove the piston rings using a standard ring expander.

Inspection

1. The cylinders are one-piece aluminum castings with hard-chrome bores. There are no liners or sleeves. In the event of damage or wear to the chromed surface of the bore, the entire cylinder and piston must be replaced.
2. If the difference between any of the bore measurements and the standard bore diameter exceeds 0.10 mm (0.00039 in.), the cylinders and pistons must be replaced.
3. Note that cylinders and pistons are stamped with a grade mark, "A," "B," or "C". When replacing components, they must always be of the same grade.
4. Measure the diameter of the piston perpendicular to the wrist pin. The measurement should be made at the specified distance above the lower edge of the skirt, viz.: V700:18.5 mm; V750, 750 Sport, 850T/T3: 35 mm; V850: 20 mm.
5. Compare the measured piston diameter with the standard diameter for pistons of that class. If the difference exceeds 0.055–0.065 mm (0.0021–0.0025 in.), replace the pistons with new ones of the same grade class.
6. If new pistons are fitted, compare their weights if a balance is available. Pistons should be within 1.5 grams of one another. If the weight difference exceeds this, it is possible to file some material from the bottom of the skirt of the heavier piston. If this is done, ensure that there are no burrs remaining by sanding with a fine emery cloth.

PISTON RINGS

1. Side clearance (installed on the piston) is 0.030–0.062 mm (0.0011–0.0024 in.) for all rings.
2. Ring end-gap must be within 0.30–0.45 mm (0.011–0.018 in.) for compression rings, and 0.25–0.40 mm (0.010–0.016 in.) for oil rings.

Installation

1. Fit a new cylinder base gasket.
2. Assemble the rings on the piston. When installing the piston on the rod, ensure that it is installed correctly. Heat the piston as on removal. Use new wrist pin circlips.
3. Stagger the ring end-gaps 90° apart so that no two adjacent rings have the end-gaps aligned. In addition, the end gaps should not be directly in line with the wrist pin holes.
4. Coat the piston rings and piston skirt with clean motor oil before installing the cylinder. Oil the cylinder bore lightly. Compress the piston rings with the fingers or with a ring compressor while the cylinder is lowered over the piston. Take extreme care that the rings enter the bore before the cylinder is lowered.

Bottom End

CONNECTING RODS

The connecting rods are of the two-piece type, having a bolted cap to hold the big end bearing. The small end has a pressed-in bush. The rods ride side-by-side on the crankshaft.

It is possible to remove the rods with the engine in the frame. If, however, the big end bearings show more than normal wear, the crankshaft must be removed for inspection and service.

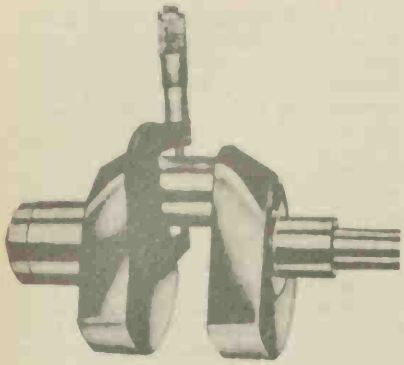
The following procedure is for the removal of the rods. If replacement of the big end bearings only is desired, they are accessible after removing the oil pan and oil pipe. Top end removal is not necessary.

Removal

1. Drain the engine oil. Remove the oil pan.
2. Remove the cylinder heads, cylinders, and pistons. Remove the oil pump filter screen assembly and the oil pipe.
3. Some models have locking tabs on the rod nuts. If these are fitted, bend them back. Remove the rod nuts. Pull off the rod cap and remove the rod. Remove the other rod in the same manner.

NOTE: *Keep the individual rod assemblies separate. Rods and caps are not interchangeable.*

Con rod assembly



Inspection

1. If replacement of the bushing is necessary, drive the old one out of the rod with a punch. Press in the new bushing, drill the oil hole, and ream it to the correct size of 22.020–22.041 mm (0.8669–0.8678 in.)
2. If the big end bearings are damaged in any way, the crankpin should be measured for possible wear to determine the size of the replacement bearings. This necessitates removing the crankshaft.

The crankpin must have an almost mirror-like finish. If any imperfections are noticed, it must be ground and the correct oversized bearings fitted.

3. Big end bearing clearance should be 0.011–0.061 mm (0.0004–0.0024 in.) for all models except the 850T/T3, which is 0.030–0.054 mm (0.0012–0.0.0022 in.).

CAUTION: *Some 850T and all T3 models have specially treated (hardened) crankpins which must not be ground down for the fitting of oversized bearings. Be sure to check with a*

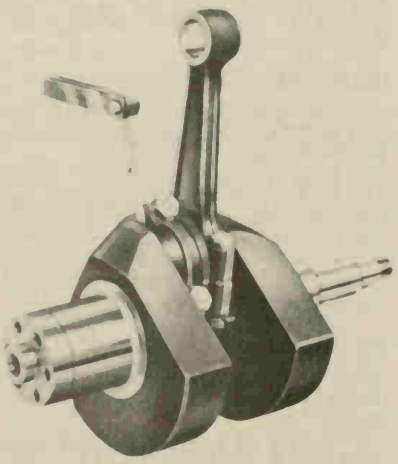
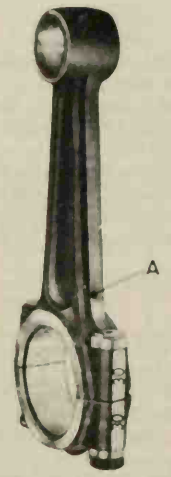
4. If the crankpin is reground, the shoulder relief radius must be restored. This should be 1.5 mm (0.059 in.) for the V700, V750, and V850; 2.0–2.5 mm (0.078–0.090 in.) for the 750 Sport and 850T models without hardened crankpins.



5. With the rods assembled on the crankshaft, check the lateral movement. If the bearings are in good condition, this should be 0.011–0.061 mm (0.0004–0.0024 in.)

6. Check the con rod side clearance. This should be 0.3–0.5 mm (0.012–0.020 in.).



7. Check that the rod is not bent. The big and small ends must be within 0.03 mm (0.0012 in.) of true, or the rod must be replaced.

8. If new rods are fitted, they should be weighed complete with bearings, bolts, and nuts. Rod assemblies must be within 3 g of each other. If a difference greater than this is noted, select another rod for use, until the weights are matched.

Installation

1. Be sure the big end bearing is well lubricated before fitting. New rod nuts should always be used.

2. When installing the rods, ensure that the oil hole on the side faces *upwards* for the left-hand cylinder's rod,

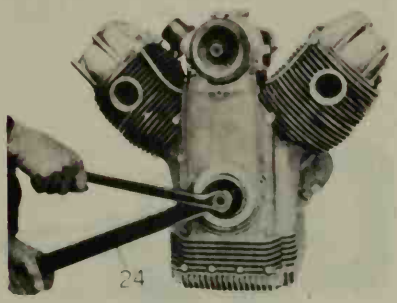
3. When fitting the rod caps, ensure that the milled side of the cap is adjacent to the milled side of the rod. On some models numbers are printed on one side of the cap and the rod, and these must align.

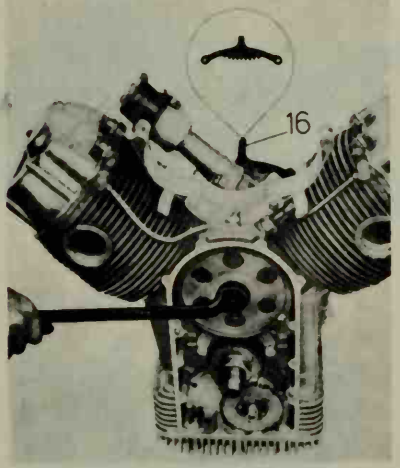
4. Torque the rod nuts to 33–35 ft lbs for 750 Sport and 850T/T3 models, 25 ft lbs on other models.



Timing Chest

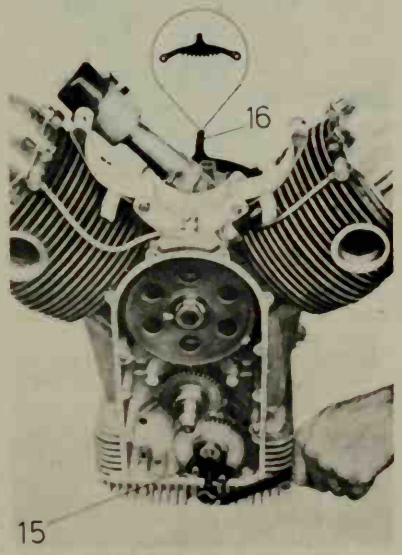
V700, V750, V850

Disassembly



Although it is possible to remove the timing gears without removing the engine from the frame, a special tool will be needed to set the valve timing if this is done. Refer to the "Valve Timing" section if such a tool is available. If it is not, removal of the engine is necessary.

1. Remove the engine from the frame.
2. Remove the generator belt cover and belt. The belt can be removed by withdrawing the three bolts which secure the outer half of the driving pulley.
3. Secure the clutch assembly with the special tool (No. 12911801) or a suitable substitute, then remove the nut which secures the inner half of the generator driving pulley and remove the pulley half. Then mount either the special tool (No. 12905300 which is indicated by No. 24 in the accompanying illustration), or a suitable substitute, to the pulley hub and remove the crankshaft nut.



Removing the pulley hub

4. Remove the screws which secure the timing cover to the crankcase, then remove the cover. Tap the cover gently with a wood block and hammer to break its seal, if necessary. Remove the seal ring from the cover if necessary.
5. Remove the cam wheel securing nut, then remove the cam wheel. The clutch should still be secured as directed in Step No. 3 by the special tool (16).
6. Remove the oil pump gear from its tapered shaft with the pump gear puller (No. 32906302 which is indicated by No. 15 in the accompanying illustration) or a suitable substitute. The clutch must be secured by the special tool (16).
7. Remove the crankshaft timing gear from the end of the crankshaft. The gear is a keyed on press fit and must be pulled with a suitable puller.

Removing the cam wheel nut

Removing the oil pump gear

Assembly

1. Assembly is in the reverse order of disassembly.
2. Consult the "Valve Timing" section for instructions on installing the three timing chest gears.
3. When installing the timing cover, some provision must be made to protect the seal ring. This is easily done by using the special tool (No. 12908300).
4. Install and adjust the generator belt as described in "Maintenance."

750 SPORT, 850T/T3

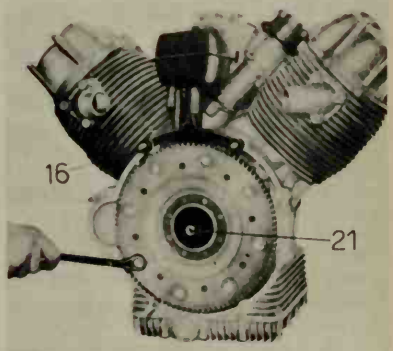
Early models of this series are fitted with the same type of gear drive assembly as the V700, V750, and V850. Later models have a chain-driven assembly.

Disassembly

Remove the engine from the frame.

2. Remove the alternator cover. Detach the alternator brush spring from the brush. Remove the screws which secure the stator and remove it. Remove the rotor allen bolt. Use the special puller (No. 14906600) to remove the alternator rotor.
3. For models with gear-driven valve timing, the rest of the procedure is essentially the same as outlined above for the V700, V750, and V850. (See Step 4 and following). It is necessary to prevent the crankshaft from turning, and this may be accomplished by locking the transmission output shaft in place, or by removing the transmission and using the special clutch holding device (No. 12911801).
4. On models with chain-driven timing, remove the sprocket nuts and pull off the sprockets together.

Assembly



1. Assembly is the reverse of disassembly.
2. Refer to the "Valve Timing" section, following, to install the gears or sprockets correctly.
3. When installing the timing cover, a guide is available to prevent damage to the oil seal.

Clutch

ALL MODELS

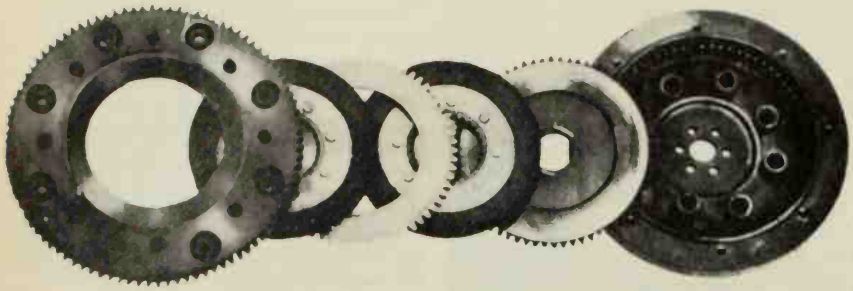
Removal

1. Remove the engine from the frame. Unbolt the transmission unit.
2. Secure the starter ring gear using either the factory tool (No. 12911801 which is indicated by No. 16 in the accompanying illustration) or a suitable substitute.

Removing the starter ring gear

Remove the bolts which secure the ring gear to the flywheel, then remove the clutch assembly.

NOTE: *The bolts must be removed evenly in a crossed pattern to avoid deforming the pressure plate.*



3. Remove the bolts which secure the flywheel, which serves as a clutch hub to the crankshaft, and remove the flywheel.

The springs should be pressure tested to check their efficiency. The following are the specificiations:

V700

With the spring compressed to 20 mm (0.7874 in.), the load should be 16 ± 10% kg (35.27 ± 10% lbs).

With the spring compressed to 17 mm (0.6692 in.), the load should be 24 ± 10% kg (52.9 ± 10% lbs).

Clutch assembly

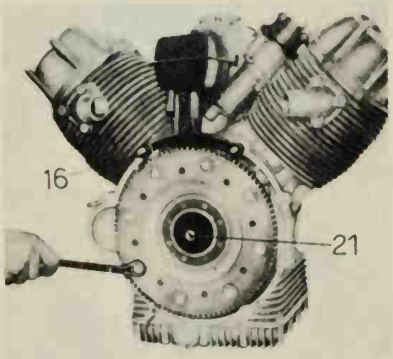
OTHER MODELS:

With the spring compressed to 20 mm (0.7874 in.), the load should be 21 ± 25% kg (46.3 ± 25% lbs).

With the spring compressed to 17 mm (0.6692 in.), the load should be within 28.7–29.7 kg (64.6–66.8 lbs).

5. Each friction plate should be 8 mm (0.3149 in.) thick as measured at a point on which there is friction material and the plates must be replaced if worn down to 7.5 mm (0.2953 in.).

Installation



1. Assembly is basically in the reverse order of disassembly.

2. Secure the flywheel to the crankshaft by means of bolts and lockwashers, then torque the bolts down to 30 ft lbs.

3. Insert the clutch springs into their housings in the flywheel, then mount the pressure plate so that the punch-marked tooth on the pressure plate is in alignment with the arrow marked on the flywheel.

NOTE: *There is an arrow on the flywheel which indicates TDC and which serves as a reference mark for assembling the clutch pressure plate.*

4. Mount the clutch dismantling and assembling tool (No. 12906500 which is indicated by No. 21 in the accompanying illustration) on the crankshaft, screwing it down enough so the clutch plates and ring gear can be so positioned that the securing bolts can be screwed down into the flywheel. The flywheel's motion must be blocked by using either the factory tool (No. 12911801) or a suitable substitute. Tighten ring gear bolts to 22 ft lbs. Remove the dismantling and assembling tool.

Installing the starter ring gear

NOTE: *The purpose of the dismantling and assembling tool is to properly align the teeth of the plates in the hub so the bolts will be able to be turned down into the flywheel.*

5. Complete the assembly in the reverse order of disassembly, then adjust the clutch.

CRANKSHAFT AND CAMSHAFT

Removal

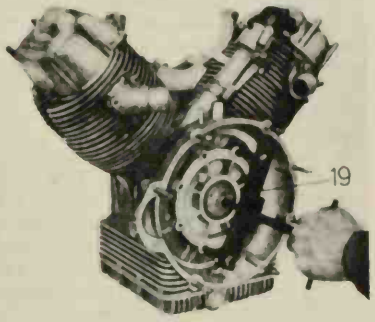
1. Remove the engine from the frame. Remove the transmission.

2. Remove the cylinder heads, cylinders, and pistons. Remove the timing chest and the gears or sprockets therein. Refer to the appropriate preceeding sections.

3. Remove the clutch assembly and the flywheel. Remove the distributor shaft (generator models) or the points assembly and housing with shaft (alternator models).

4. Remove the cam tappets from the crankcase.

NOTE: *Mark the tappets so that they can be installed in their original locations.*

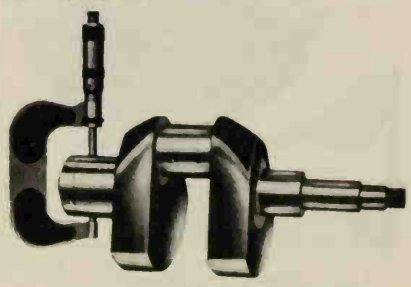


5. Remove the oil pan. Unbolt and remove the oil pipe and the oil pump filter screen assembly. Remove the oil pump.

6. Unbolt and remove the connecting rods.

7. Remove the camshaft flange (timing side) and take out the cam.

8. Remove the flywheel side crankshaft flange bolts, and use the special tool (No. 12913600) to remove the flange from the housing. Remove the crankshaft.

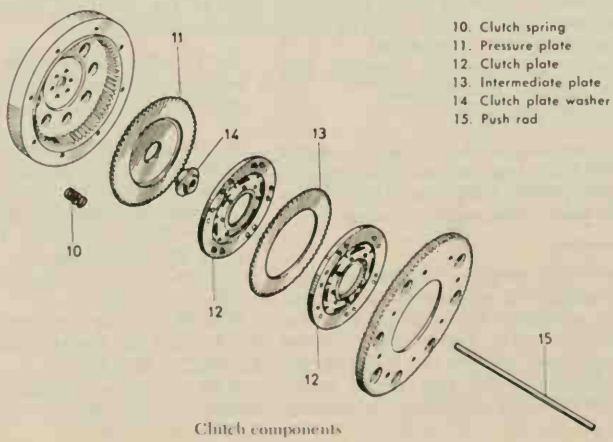


9. Remove the timing side flange from the crankcase.

Removing the main bearing flange

Inspection

1. Measure the diameter of the timing and flywheel side main bearing journals, and then the inside diameters of the main bearings. Two measurements should be made of each journal, 90° apart, to check for ovalization.



Measuring main bearing diameter

Bearing clearances must be within the following limits:

Crankshaft-to-timing side main bearing: 0.025–0.057 mm (0.00098–0.00224 in.).

Crankshaft-to-flywheel side main bearing: 0.030–0.068 mm (0.00118–0.00270 in.).

2. If the bearing clearances are not within the proper limits, new bearings should be fitted. If the journals are scored or are not within the standard values given, they should be ground down, and undersized bearings fitted. This must be done according to the following specifications.

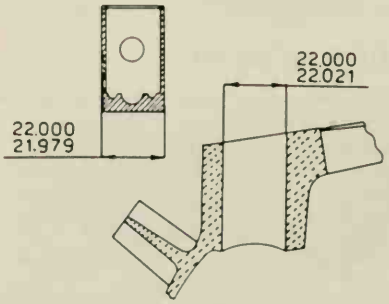
3. If the crankshaft journals are ground to an undersize, the relief radius must be restored. This should be 3 mm (0.118 in.) for the flywheel side and 1.5–1.8 mm (0.058–0.070 in.) for the timing side.

4. Check the dimensions of the camshaft bearing journals against the inside diameters of the housings against the following specifications.



V700, V750, V850:

	Camshaft Journals Diameter	Housing in Crankcase Diameter	Fitting Clearance
Timing side	46.975–47.000 mm (1.8494–1.8504 in.)	47.025–47.064 mm (1.8511–1.8529 in.)	0.025–0.089 mm (0.0009–0.0035 in.)

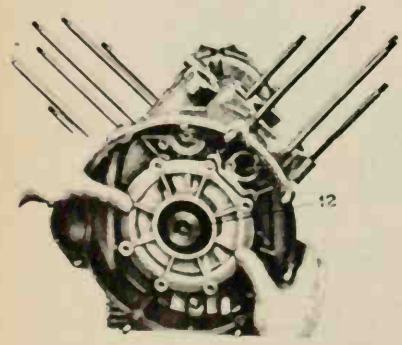
5. Inspect the tappets for signs of wear, scoring, or other damage, and replace them if necessary. Slight score marks can be removed with fine emery paper. The tappet-camshaft contact area must be perfectly smooth or both components will wear out quickly. The tappets must move smoothly in their guides with no hesitation or binding, and the guides must not be scored or worn. Oversized tappets are available, and the guides must be reamed to the proper size if these are going to be used. Compare tappet and guide sizes against the following specifications:



Tappet and guide dimensions

Assembly

1. The use of new oil seals is recommended, regardless of the apparent condition of the original seals. New woodruff keys should also be used.
2. All components should be coated with plenty of clean engine oil during the assembly procedure. This is especially critical of bearing surfaces.
3. Mount and secure the timing side main bearing and flange assembly.
4. Install the crankshaft, then the flywheel side main bearing and flange. The lubrication passages in the flange must be aligned with the passages in the crankcase, and the seal in the flange should be protected during installation with a guide (Tool No. 12912000).

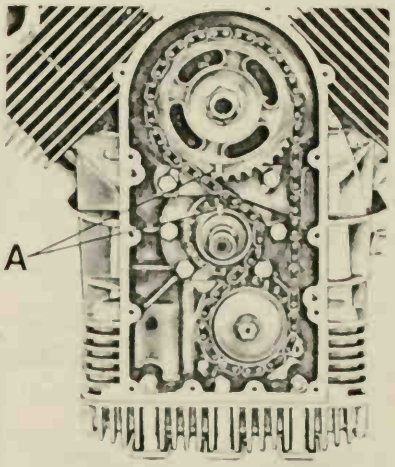
Mounting the flywheel side main bearing flange

5. The remainder of the assembly procedure is the reverse of disassembly.

Refer to the "Valve Timing" section following to properly install the timing gears or sprockets.

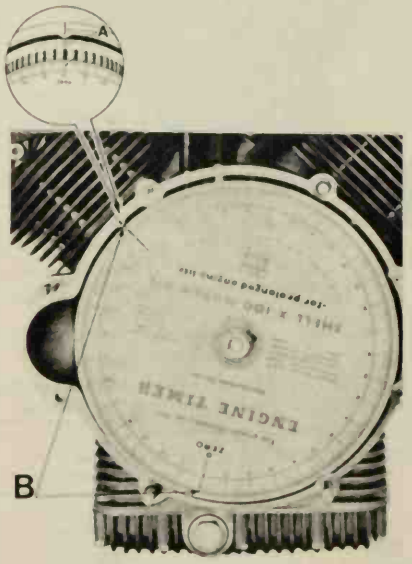
Valve Timing

CHAIN DRIVEN TIMING



1. Correct valve timing is easily obtained by aligning the marks on the crankshaft and camshaft sprockets when the sprocket and chain assembly is installed.

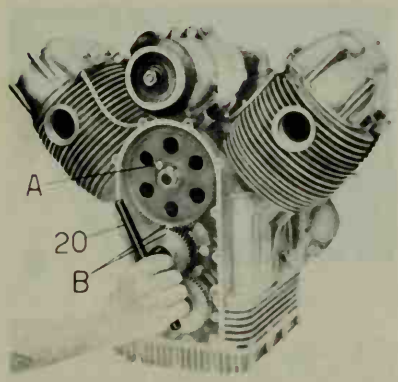
GEAR DRIVEN TIMING



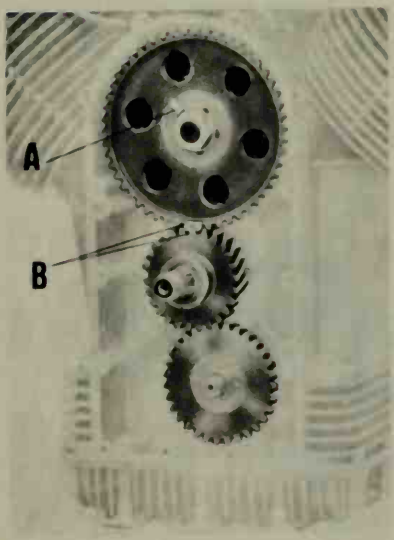
V700, V750, V850

The intake valve opens at 24° BTDC and closes 58° ABDC; the exhaust valve opens at 58° BBDC, and closes 22° ATDC.

1. Adjust the tappets to 0.5 mm (0.0195 in.). Rotate the flywheel until its timing mark is in alignment with the timing mark on the crankcase.
2. Mount a degree wheel on the flywheel in such a manner that the zero on the degree wheel, the arrow on the flywheel, and the line of the crankcase are all aligned. (See (A) on the accompanying illustration.)



Timing marks aligned (Chain-driven timing)



Degree wheel aligned for valve timing (All except Sport)

3. Rotate the flywheel 122° (the distance indicated by (B) in the illustration) in the direction of normal engine operation until the exhaust valve of the left-hand cylinder begins to open.
4. At this point, the only timing gear which should be installed is the oil pump gear. Mount the crankshaft timing gear on the crankshaft, then, using a screwdriver, rotate the camshaft counterclockwise until the rocker arm on the exhaust valve of the left hand cylinder begins to touch the valve.
5. Mount the cam wheel on the camshaft in such a manner that the dowel slots in the camshaft and cam wheel will align without necessitating moving the crank or camshaft, and insert the pin.

NOTE: *It is a good idea, when installing new gears, to mark the teeth which are engaged in the cam wheel and the crankshaft timing gear, and the point on the wheel where it is keyed to the shaft with a daub of paint for future reference.*

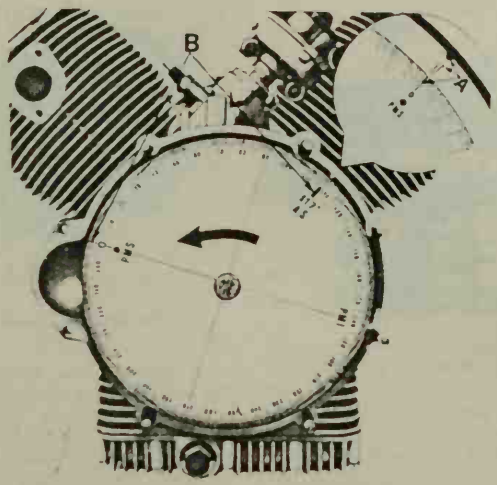
Aligning timing marks

Marking the gears for future reference

6. Adjust the tappets to their correct specifications.

750 Sport

The following procedure applies to Sport models with gear-driven timing.



The camshaft specifications are as follows: intake valve opens 40° BTDC, closes 70° ABDC; exhaust valve opens 63° BBDC, closes 29° ATDC.

1. Set all valves to a clearance of 0.5 mm (0.019 in.). Rotate the flywheel until the arrow on it aligns with the projection on the crankcase (clutch side). This positions the right-hand cylinder at TDC, with both valves closed.

2. Fit a degree wheel to the flywheel, aligning the TDC mark of the degree wheel with the flywheel arrow and the crankcase projection.

3. Turn the flywheel 117° in a counterclockwise direction. At this point, the exhaust valve for the right-hand cylinder will begin to open once the timing is correctly set.

4. Install the oil pump gear; then fit the crankshaft timing gear and secure it. Use a screwdriver to turn the camshaft in a counterclockwise direction until the right cylinder's rocker arm just touches the exhaust valve.

Degree wheel alignment for valve timing (V7 Sport)

5. Carefully install the camshaft gear so that the dowel pin can be inserted into the camshaft without moving either the crankshaft or the camshaft.

6. Mark the teeth of the gears that engage, and the position of the dowel pin on the camshaft gear with daubs of paint to facilitate any future retiming. Secure the camshaft gear.

7. Set the valve clearance to 0.22 mm (0.0086 in.). Check the opening and closing of the valves against the cam specifications.

Alternate Method

A special tool is designed for this job to transfer the timing marks on the fitted camshaft gear to a new replacement.

1. Remove the timing gears.

2. Insert the pin of the special tool (no. 12913800, 25 in the illustration) into the camshaft gear slot. Loosen the tool's bolt, and turn the arm so that it indicates the two marked teeth on the cam gear. Tighten the bolt, and remove the tool from the old gear.

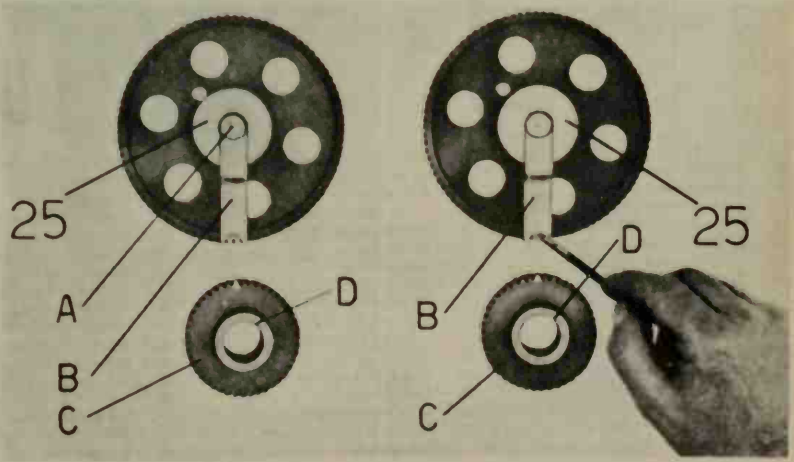
3. Fit the tool to the new replacement camshaft gear, inserting the pin into each of the five slot until the notch on the tool's arm will bracket two gear teeth perfectly.

4. Mark these two teeth with paint. Also mark the slot into which the tool's pin was inserted.

5. If the crankshaft gear is being replaced as well (it should be if the cam gear was worn or damaged), copy the index mark onto the replacement gear by counting the number of teeth between the gear's keyway and the marked tooth.

6. Install the crankshaft gear, then the cam gear, inserting the pin into the marked slot, and ensuring the marked teeth of the two gears engage when the engine is rotated.

NOTE: *It is important that the camshaft not be disturbed while the gears are removed if this procedure is used.*



Transmission

The V700 and V750 use a four-speed transmission, while a five-speed is found on the 750 Sport and 850 models.

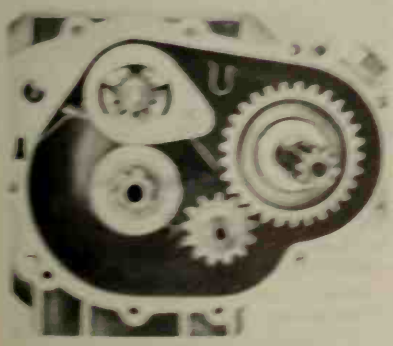
14. Remove the clutch shaft complete with the cush drive assembly, then remove the two cush drive plate keepers, the cush drive plate, the cush drive spring, the sliding sleeve, and the clutch shaft-to-mainshaft driving gear. The easiest way to disassemble this assembly is by clamping the shaft on a press or in a wood-jawed vise and using either the special tool (No. 12905900 which is indicated by No. 23 in the accompanying illustration), or a suitable substitute to compress the spring.



Disassembling the clutch shaft

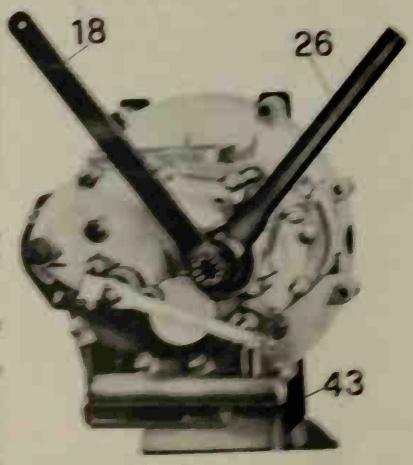
   e. Drift out the layshaft bearing with an appropriate drift.

NOTE: *Heating the cases to about 150–160° C (300–350° F) will make removing the bearings considerably easier.*



Five Speed Models

1. Follow steps 1–7 in the "Four Speed Models" section. The transmission should be in its Neutral position.

Five-speed transmission assembled

NOTE: *When loosening the layshaft securing nut, use the special tools designed for use on the V850 rather than those listed in the "Four-Speed Models" section. These are Nos. 12907100 and 14905400.*

Loosening the layshaft nut

3. Remove the shifter fork rod, then remove the high gear shifter fork.

4. Remove the high gear sliding dog gear from the layshaft, then remove the layshaft high gear.

5. Remove the mainshaft high gear along with its roller cage and bushing in the following manner:
   a. Depress the stop pin down into its housing using a suitable pointed instrument, then turn the bushing in either direction and withdraw the gear, complete with roller cage and bushing, to within reaching distance of the shaft hole.
   b. Place your left thumb against the spring loaded stop pin, to prevent it from springing off into the cosmos, and at the same time withdraw the gear assembly with your right hand.
   c. Remove the stop pin and spring assembly.

6. Remove the breather plug from the top of the transmission housing and remove the spring. The pawl will remain in the housing for removal only after the entire assembly has been taken down.

7. Remove the screws which secure the neutral indicator to the housing, then remove the indicator.

8. Remove the shifter drum and rod, taking careful notice of the way in which the shims are positioned on the drum and the way the drum is positioned in the gearbox, so they may be replaced in their original locations, then remove the rod from the drum.

NOTE: *Tap the end of the shaft gently with a soft mallet if it is reluctant to leave its seat.*

14. Remove the inner roller bearing race and the spacer nut from the clutch shaft using either the special puller (No. 14928500 which is indicated by No. 29 in the accompanying illustration) or a suitable substitute.

15. Install the clutch shaft in a wood-jawed vise, then use either the special tool (No. 12905900), or a suitable substitute, to compress the spring enough so the keepers can be removed; then remove the tool and slip off the cush plate, spring, sliding sleeve, and the intermediate gear.

NOTE: *Use a screwdriver with a daub of grease on its tip to remove the keepers.*

16. Remove the bearings from the

d. Remove the clutch shaft seal, the lockplate securing bolts, and the lockplate, then drift out the clutch shaft bearing.

17. Remove the shifter merchanism from the transmission cover by carefully tapping the assembly free with a soft mallet, then remove the shifter return spring, the spring guide pin, the operating pawls, the pawl return springs, and the shifter adjusting screw and locknut.

If the pawls must be removed, do so by removing the pins with the aid of a 3–4 mm (0.11–0.15 in.) tool; the pawl springs will come out with the pins. A 10 mm (0.39) reamer may be used to ream out the pawl housings.

18. Remove the bearings from the gearbox cover in the following manner, especially if they have been secured with Loctite®:

a. Place the cover in an oven and heat it up to 150–160° C (300–350° F).
b. Remove the mainshaft bearing.
c. Remove the clutch shaft bearing.
d. Remove the layshaft seal and the lockplate securing screw, then remove the lockplate.
e. Remove the layshaft bearing.

INSPECTION

1. Inspect the fifth gear bushing retainer and spring for signs of wear, damage, or, in the case of the spring, a collapsed condition and replace them as necessary. The spring should show a load of 1.40 kgs (3.08 lbs) when compressed to a length of 8 mm (0.031 in.).

2. Check the clearances between the layshaft gear bushings and the shaft (V700 and V750 models). The clearances should be as follows:

a. The inside diameter of the first, second, and third gear bushings must be within 27.040–27.061 mm (1.0646–1.0655 in.).
b. The outside diameter of the layshaft bushing support for first, second, and third gears must be within 26.987–27.000 mm (1.0624–1.0630 in.).
c. The bushing-to-layshaft fitting clearance must be within 0.040–0.074 mm (0.0016–0.0028 in.).

f. The clearance between the fourth gear and its floating bushing must be within 0.040–0.082 mm (0.0016–0.0032 in.).

4. Inspect the clutch shaft assembly for signs of wear or damage and replace the necessary components. The sliding sleeve must be able to slide smoothly and freely and the engaging teeth must be devoid of chips, score marks, or other damage.

5. Inspect the cush plate assembly, making sure that the retainer is not cracked or damaged, the plate grooves are not rough or damaged, and that the drive spring is not collapsed or damaged, and replace any parts as necessary.

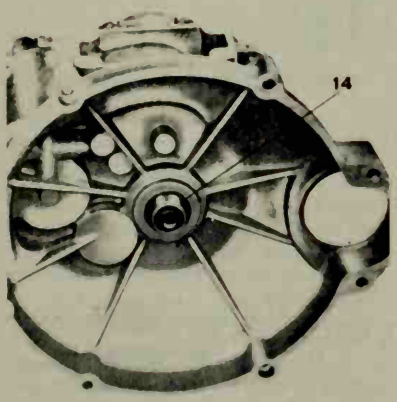
ASSEMBLY

Four Speed Models

1. Assembly is basically in the reverse order of disassembly. Lubricate all parts, other than those surfaces on which a sealant is used, with clean oil as you put them together and make certain that all parts are perfectly clean.

2. Press all bearings into the cover and case using light applications of GREEN Loctite® at your own discretion. Make absolutely certain that no Loctite® gets into the bearings. When installing the layshaft bearing in the case, make sure you use a bottom plate to protect the fourth gear floating bushing.

CAUTION: *The Loctite® must be allowed to set for at least 12 hours before you continue with the assembly.*



3. Install the clutch shaft seal ring on the gearbox.

4. Install the mainshaft with the two thrust washers and the intermediate washer between the roller bearing and the fourth gear side of the shaft.

5. Place the fourth gear, its floating bush, and the thrust washer on the bearing; then insert the assembled layshaft (except for the first gear) through the thrust washer and gear and into the bearing.

6. Install the assembled clutch shaft assembly in the gearbox, using either the special tool (No. 12910700 which is indicated by No. 14 in the accompanying illustration) or a suitable substitute, to protect the seal ring.

NOTE: *Failure to install the shaft correctly will result in damage to the seal ring and eventual oil leakage on the clutch.*

Protect the seal before installing the clutch shaft

7. Install the shifter forks to the two sliding dog gears, install the shifter drum, then insert the fork ends in the drum grooves.

8. Slip the fork shaft through the forks, then mount the camplate on the shaft.

9. Rotate the shifter drum until the shifter pawl enters the fourth gear position hole and the sliding dog gear engages the second gear.

10. Install the assembled shifter inner body which includes the springs, plungers, and pawls.

11. Slip the first gear and an adjusting washer on the layshaft.

12. Install the oil pick-up plate and the neutral indicator unit in the gearbox; then mount the gearbox cover and a new cover gasket, making sure the indicator doesn't interfere with the mating of the box and cover. A light coating of a gasket sealer may be used at your discretion.

NOTE: *When securing the cover screws, do so evenly in a cross pattern to avoid deforming the cover gasket.*

13. Mount the speedometer driving gear, spacer, and lockwasher on the layshaft; then install the lock ring using either the special tools (Nos. 12907100 and 12905400) or suitable substitutes. Secure the ring by bending the locking tab in the lock ring slot.

14. Assemble the sector quadrant and shifter shaft assembly, the shifter return spring and the offset adjusting screw, along with its washer and locknut, to the shifter cover; then mount the cover assembly using a new gasket and making sure that the quadrant is engaging the shifter inner body. A light coat of a gasket sealer may be used at your discretion.

NOTE: *When securing the cover, tighten the short and long screws evenly in a cross pattern to avoid deforming the cover gasket.*

15. Mount the gear shifter operating lever on the shifter shaft, securing it by means of the two circlips which fit in the clutch shaft grooves.

16. Install the clutch rubber tube, pressure rod, inner body, cage and outer body, and seal ring; then mount the clutch operating lever to the gearbox by means of its pin and cotterpin.

17. Check the shift mechanism. If shifting is not satisfactory, adjust by loosening the locknut and turning the adjusting screw. This adjuster is located on the rear cover, above the clutch lever.

Five Speed Models

1. Assembly is basically in the reverse order of disassembly. Lubricate all parts, other than those surfaces on which a sealant is used, with clean oil as you put them together and make sure that all parts are perfectly clean.

2. When installing the bearings, it is recommended that a light coat of GREEN Loctite® be used on the outer races and bearing housings. Be very careful to avoid getting any Loctite® in the bearings and allow them to set for about 12 hours before continuing with the assembly. Install the bearings as follows:

a. Install the clutch shaft bearing into its gearbox housing.

b. Press the outer layshaft bearing race into its gearbox housing.

c. Install the mainshaft bearing in its gearbox housing.

d. Press the layshaft bearing in its housing in the gearbox cover.

e. Install the mainshaft bearing in its cover housing.

f. Install the clutch shaft bearing.

3. Install the layshaft bearing retainers in the gearbox cover, making sure that they seat absolutely flush with the outer bearing races. Mill away any projections which may prevent a perfect seal and use a light coat of green Loctite®, taking care not to allow any of it to penetrate the bearing.

NOTE: *Use only the modified type retainers (part No. 14213802) for the best results.*

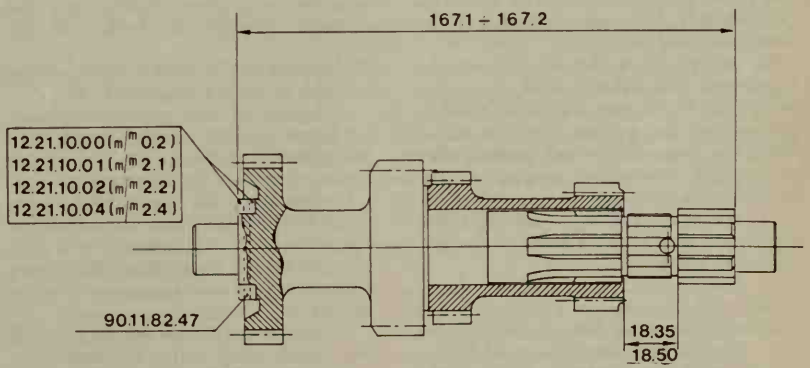
4. Install the clutchshaft seal in the gearbox.

5. Install the layshaft seal in the gearbox cover.

6. Install the selector shaft seal in its housing in the gearbox cover.

7. Assemble the shifter body by inserting the pawls and springs and securing them to the shifter body with flexible pins; then install the shifter quadrant shaft, gear, and return spring to the shifter body and mount the assembled body to the gearbox cover.

8. Shim up the mainshaft so the distance between the cover bearing and the gearbox bearing is within 167.1–167.2 mm (6.578–6.582 in.). Shims are available in the following sizes: 0.2, 2.1, 2.2, and 2.4 mm (0.0788, 0.8274, 0.8668, 0.9456 in.) and may be fitted on the gearbox end of the shaft with bronze spacers between them. The part numbers are given in the accompanying illustration.



9. Press the mainshaft roller bearing inner race onto the shaft using either the special tool (No. 14928600 which is indicated by No. 40 in the accompanying illustration) or a suitable substitute.

10. Assemble the following components on the layshaft gearbox end:

a. Slip the second gear bushing on the shaft so the bushing head faces the transmission cover.

b. Fit the second gear roller cage on the second gear bushing, then mount the second gear on the cage so its engaging dogs are facing the gearbox cover.

c. Slip the third gear bushing on the shaft so its head faces the second gear, assemble the third gear roller cage on the bushing, then install the third gear on the roller cage so its engaging dogs are facing the gearbox.

d. Place a shim on the shaft, install the fixed sleeve on the shaft with its stepped down end facing the third gear, then slip the third and fourth gear sliding sleeve onto the shaft with its stepped down end facing the third gear.

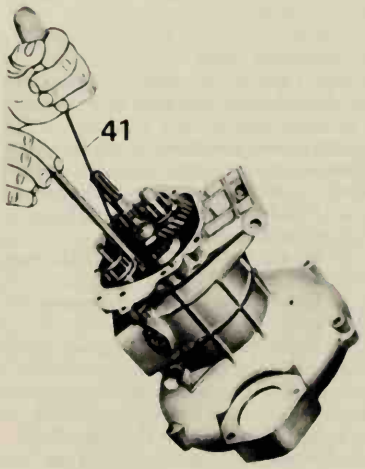
e. Slip the fourth gear bushing on the shaft, install the roller cage on the bushing, then position the fourth gear on the shaft so its engaging dogs face the sliding sleeve.

11. Assemble the following components on the layshaft gearbox cover end:

a. Slip the first and second gear engaging sleeves on the shaft.

b. Position the first gear bushing on the shaft so its head faces second gear, fit the first gear roller cage on the bushing, then install the first gear on the roller cage.

c. Position the seal in its groove in the shaft, then slip the fourth gear on the shaft so its stepped down end is fitted on the seal ring.



12. Shim the layshaft on the fourth gear side until the distance between the shims and the fourth gear is within 144.7–145.2 mm (5.692–5.715 in.). This can generally be accomplished with between two and four shims.

13. Mount the roller bearing on the fourth gear end of the layshaft, secure the nut on the fourth gear end of the shaft by hammering the nut tang with a chisel along the line of the shaft groove, then mount the assembled layshaft in the transmission housing.

14. Assemble the first, second, third, and fourth gear shifting forks on the layshaft dog gears.

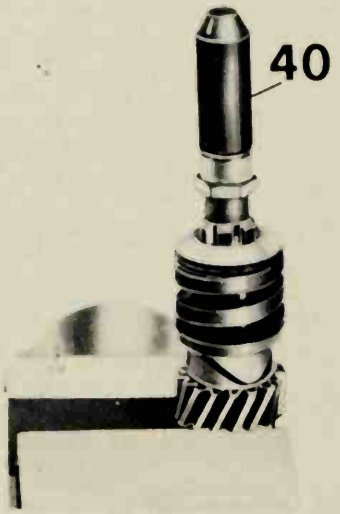
15. Install the splined shifter drum, along with its shaft and a spacer, in the gearbox. Then look through the hole in the ratchet pawl to see if the pawl hole is aligned with one of the six holes in the drum. If the holes are misaligned, replace the spacer with larger or smaller ones until both holes are in perfect accord.

16. Position the nubs of the shifter forks in the drum grooves using either the special tool (No. 14929300 which is indicated by No. 41 in the accompanying illustration) or a suitable substitute.

Fitting the shifter forks to the drum

17. Temporarily secure the peg, spring, and cap in their gearbox housing.

18. Slip the shifter fork retaining rod through the fork eyes.



19. Mount and secure the neutral indicator to the gearbox, making sure that the blade contacts the button on the drum.

20. Assemble the clutch shaft assembly in the following manner:

a. Install the idle gear so its engaging dogs face the gearbox cover, then position the coupling sleeve so its engaging dogs face the idle gear.

b. Slip the cush spring and spring plate on the shaft, then use either the special tool (No. 12905900), or a suitable substitute, to compress the spring enough so two new keepers can be installed.

c. Secure the spacer nut, then install the clutch shaft roller bearing inner race in the cover using either the special tool (No. 14928600 which is indicated by No. 40 in the accompanying illustration) or a suitable substitute.

Installing the clutch shaft bearing inner race

d. Install, on the gearbox end of the shaft, the oil seal in its groove, and the oil scoop between the shaft and gearbox bearing; then mount the shaft assembly in the gearbox bearing and retaining ring.

21. Assemble the mainshaft assembly in the following manner:

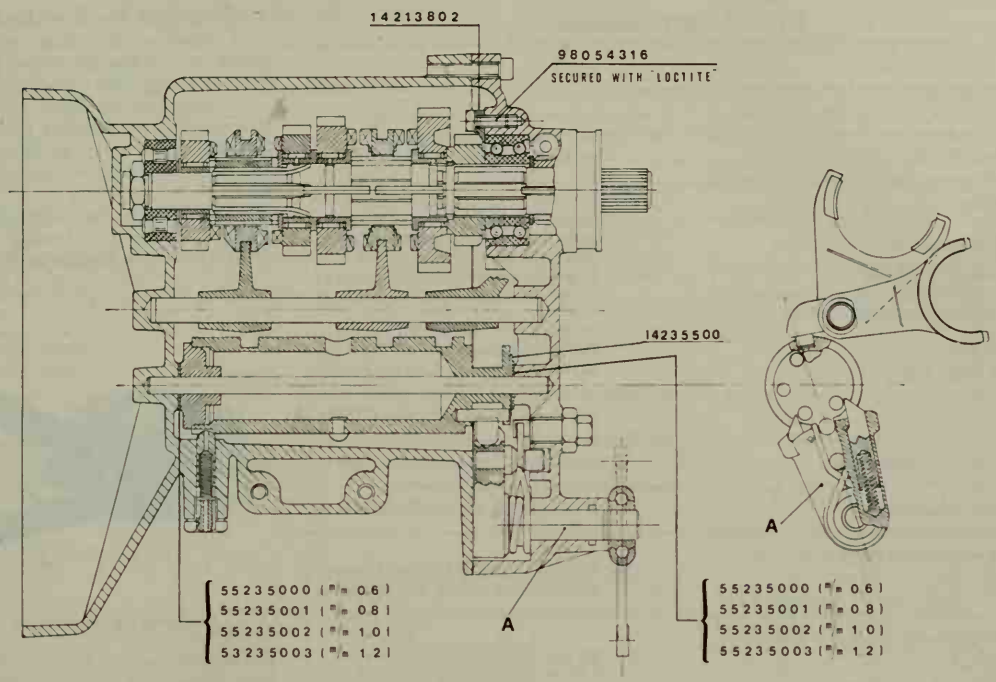
a. Mount the fifth gear roller cage and gear on the bushing, then slip the gear, cage, and bushing assembly on the splined portion of the shaft.

b. Mount the spring in its drilling in the shaft, then position the stop pin on top of the spring.

c. Depress the spring with the thumb of your left hand while slipping the fifth gear assembly over it, then rotate the bushing to either the right or left until the stop peg seats into one of the bushing's six splines.

d. Slip the fifth gear engaging sleeve and shifter fork onto the shaft, so the fork eye slips over the fork rod, then engage the fork nub in the drum groove.

22. Assemble the gearbox cover in the following manner:



a. Install the retaining washer on the shifter drum along with one or more shims.

b. Shift the drum into the neutral position, place a new cover gasket on the mating surface, mount the cover while tapping it lightly with a soft mallet to properly seat all of the shafts and mating surfaces, then lightly screw in the four cover screws.

NOTE: *A sparing application of a suitable gasket sealer may be used at your own discretion, but make sure none of it gets inside the gearbox.*

c. Slip the shim, speedometer drive gear, and the drive gear stop ball onto the layshaft, then temporarily secure the layshaft securing nut.

d. Mount either the special tool or any suitable substitute which you can use to shift the transmission, onto the shifter shaft.

Shimming the gearbox

e. Loosen the locknut and rotate the adjusting nut on the rear cover until a suitable adjustment is achieved in which all gears, including Neutral, can be easily engaged. If ease of shifting cannot be attained, remove the gearbox cover and add or remove spacer shims from between the gearbox and the shift drum to alleviate shifting problems related to First and Third gears, or between the gearbox cover and the drum to alleviate shifting problems related to Second and Fourth gears. 0.6, 0.8, 1.0, and 1.2 mm (0.023, 0.031, 0.039, and 0.047 in.) shims are available

f. Remount the cover and recheck the gearbox operation. If all of the gears engage smoothly, including Neutral, secure the layshaft nut using either the special tools (Nos. 14905400 and 12907100) or suitable substitutes, then hammer the nut with a chisel at the shaft groove to lock it into place.

g. Secure the cover mounting screws, remove the tool from the shifter shaft, and mount and secure the shift lever on the shifter shaft.

h. Secure the oil breather plug which serves to secure the gearbox spring and stop peg.

23. Mount the bearing inner body seal, inner body, safety washer, and the inner body locking nut on the clutch shaft using either the special tools (Nos. 14912800 and 14912600) or suitable substitutes, then bend one of the locking tabs into one of the locknut grooves.

24. When installing the clutch unit on the mainshaft and gearbox cover, position the small rubber tube in the shaft, mount the inner body, mount the throwout bearing on the inner body, and mount the inner body and seal on the gearbox cover. Then slip the clutch pushrod into the operating shaft at the gearbox end, mount the release mechanism on the cover along with the adjusting screw and locknut and then, using cotters and pins to secure it, install the shifter lever return spring in its housing in the cover.

25. Adjust the gearbox as described in the "Transmission Adjustment" section.

13. Remove the roller bearing cage retaining ring, drive box oil seal, wheel-to-drive box spacer, and the level plug and gasket.

14. If you wish to remove the universal double joint, gaiters, and bands, you'll have to either remove the engine and transmission assemblies from the frame or remove the swing arm assembly.

Assembly

1. Assembly is in the reverse order of disassembly. Use new gaskets, seals, and lockwashers.

Refer to the "Engine Torque Specifications Chart."

2. Replace the oil drain plug, position the rear wheel-to-drive box spacer and press the drive box oil seal into place.

3. Install the bearing cage retaining ring, roller bearing outer race, bearing cage, and inner race, then secure the bearing stop screw and plate.

4. Assemble the bevel crown to the internally toothed sleeve by means of the securing bolts and locking tabs.

5. Press the bearing and seal ring into the drive box flange, position new gaskets on the drive box and box flange, then mount the flange to the box.

NOTE: *Do not secure the locking tabs until after the bevel gear adjustment is performed as directed in the "Bevel Gear Adjustment" section.*

6. Install the front bearing, bearing spacer, distance adjusting shims, and the rear bearing into the bearing housing.

7. Mount the spacer shim and adjusting shims onto the bevel pinion and slip the pinion shank into the bearing housing, then secure it with a lock-ring and lock-ring safety washer using either the special tool (No. 12907100) or a suitable substitute.

NOTE: *After the bevel gear adjustment is carried out, secure the lock-ring by bending the lockwasher locking tab. Consult the "Bevel Gear Adjustment" section for additional information.*

8. Secure the bearing housing and bevel pinion to the drive box by means of the securing nuts and washers.

NOTE: *This must not be done until the bevel gear adjustment is carried out as directed in the "Bevel Gear Adjustment" section.*

9. Install the ball bearing to the swing arm and secure it with a circlip.

10. Install the double joint in the swing arm bearing and fit the gaiters and bands over the joint. The bands should be used to secure the gaiters on the swing arm side only.

NOTE: *If the engine and transmission have been removed from the frame, the front side of the gaiters must be secured when installed in the engine and transmission assembly.*

11. Position the circlips in their grooves in the drive shaft, then install the shaft into the double joint and bevel drive sleeve.

12. Insert the splined portion of the bevel pinion into the sleeve and secure it without locking the four bolts and lockwashers which secure the drive box to the swing arm. Then insert the rear

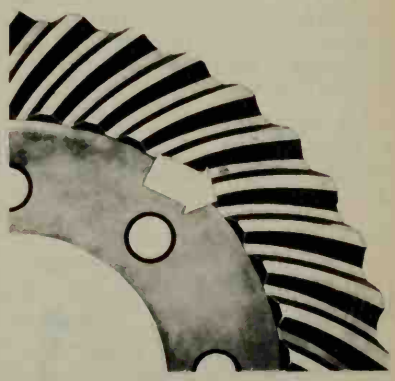
keeping the crown braked so the rotation will take place under load, so contact marks will appear on the coated surface of the crown.

b. Make sure that the contact is correct by comparing it with the accompanying illustration. If the contact marks are incorrect, go onto the next step.

3. If the contact pattern is not correct, consult the following steps and illustrations to arrive at a solution:

NOTE: *After adding or removing shims, readjust the pinion-to-crown clearance before rechecking the contact pattern.*



a. Excessive contact at the bottom of the tooth flank indicates that the pinion is too deeply inserted in the crown and this may be remedied by reducing the number of adjusting shims, or by using a thinner shim.

b. Excessive contact at the heel of the tooth indicates that the crown is too far from the pinion and this may be remedied by increasing the number of shims, or by using a thicker shim.

c. Excessive contact at the crest of the tooth indicates that the pinion is too far from the crown and this may be remedied by increasing the number of shims, or by using a thicker shim.

Oil Pump

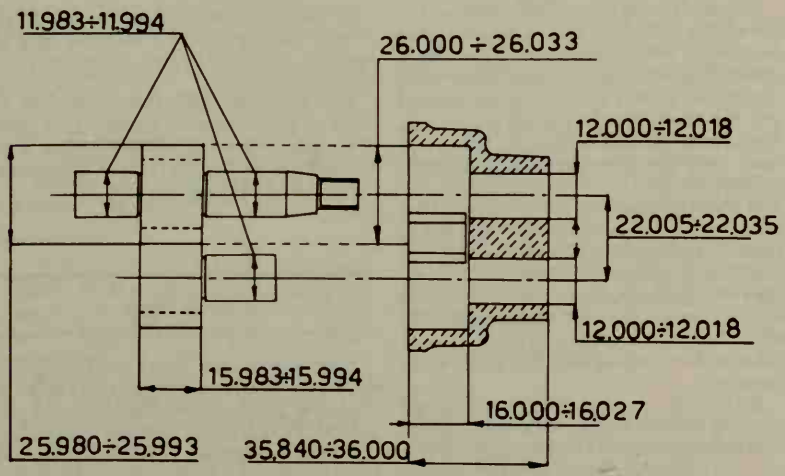
GEAR DRIVEN TIMING

Removal

1. Remove the alternator or generator drive belt and pulley. Drain the oil. Remove the timing case cover. Remove the oil pump gear using tool No. 32906302. Refer to the "Engine and Transmission" section for detailed procedures.
2. Unbolt and remove the oil pump.
3. If removal of the filter screen assembly is desired, remove the oil pan, the oil pipe (if necessary), and unbolt the filter assembly.

Lubrication system components: A, oil pipe; B, filter; C, pressure relief valve; D, oil pump

4. The oil pipe incorporates the oil pressure relief valve. Disassembly of this valve should not be undertaken as it will affect the pressure at which the valve opens.



Inspection

1. Measure the width of the pump gears and replace them if worn past their serviceable limit. The gears should be 15.983–15.994 mm (0.6293–0.6297 in.) wide.
2. Measure the depth of the gear housing in the pump body and replace the unit if it is worn greater than its serviceable limit of 16.000–16.027 mm (0.6299–0.6309 in.). The areas to be measured are indicated in the accompanying illustration.

Checking oil pump gear clearance

3. Measure the outside diameter of the pump gears and replace them as a set if worn past their serviceable limit of 25.993–25.980 mm (1.0233–1.0227 in.).
4. Measure the inside diameter of the gear housings within the pump body and replace the unit if worn past their serviceable limits of 26.000–26.033 mm (1.0236–1.0249 in.).
5. Check the clearance between the pump gear shafts and the supports upon which they ride in the pump body. The outside diameter of the gear shafts should be within serviceable limits of 11.994–11.983–11.994 mm (0.4717–0.4722 in.), and the inside diameter of the supports should measure 12.000–12.018 mm (0.4724–0.4731 in.). The clearance between the supports and the shafts must be within 0.006–0.035 mm (0.00023–0.00137 in.) or the worn components must be replaced.

Oil pump dimensions (gear-driven timing)

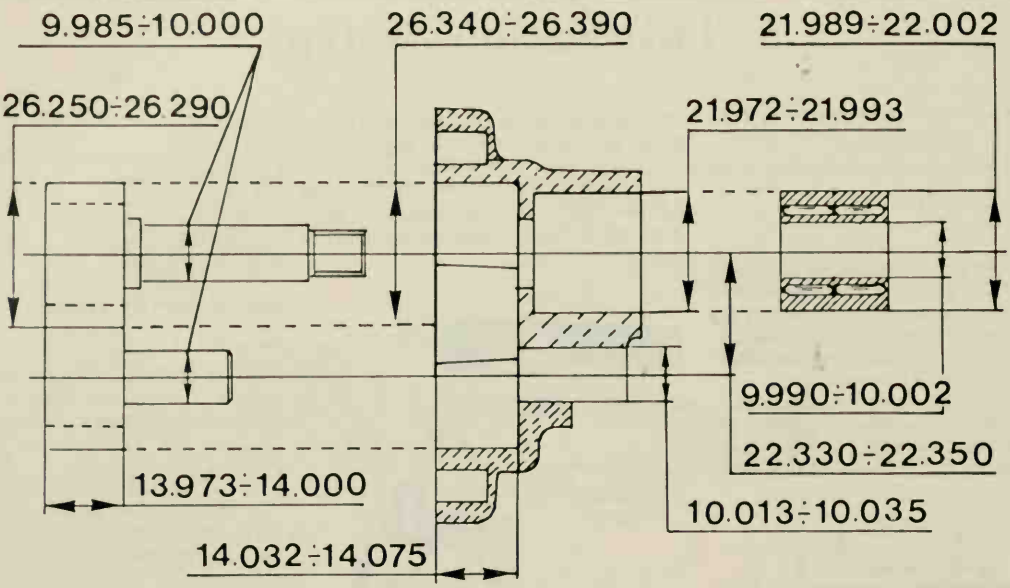
Installation

1. Soak the oil pump in clean motor oil before installation.
2. Reverse the removal procedure, using new gaskets where applicable. Torque the oil pump and filter assembly bolts to 22 ft lbs.

CHAIN DRIVEN TIMING

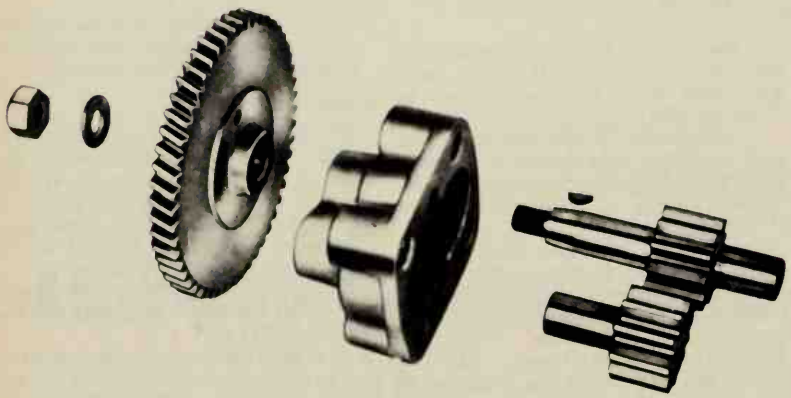
Removal

1. Drain the oil. Remove the alternator and the timing case cover. Remove the timing sprockets and chain. Refer to the "Engine and Transmission" section for detailed procedures.
2. Unbolt and remove the oil pump.
3. If removal of the filter screen assembly is desired, remove the oil pan, the oil pipe (if necessary), and unbolt the filter assembly.
4. The oil pipe incorporates the oil pressure relief valve. Disassembly of this valve should not be undertaken, as it will affect the pressure at which the valve opens.



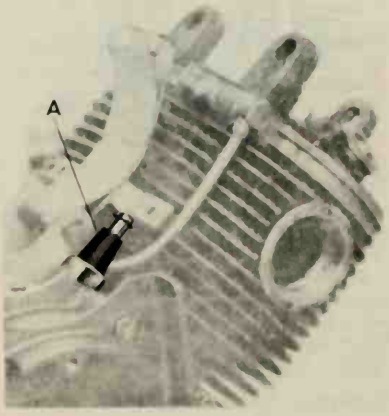
NOTE: *On some models the oil pipe and the pressure relief valve are incorporated into the oil pan casting.*

Inspection



1. The oil pump fitted to chain timing models is similar in operation to that found on the other machines, except that a double needle bearing is installed on the pump driven shaft. This is necessary because of the tension exerted by the chain on the oil pump sprocket.
2. Check the width of the pump gears. They should be 13.973–14.000 mm (0.5501–0.5511 in.).
3. Check the depth of the gear housings in the pump body. Standard value is 14.032–14.075 mm (0.5524–0.5541 in.).
4. Outside diameter of the pump gears should be 26.250–26.290 mm (1.0335–1.0350 in.).
5. The diameter of the gear housings in the pump body should be 26.340–26.390 mm (1.0370–1.0390 in.).
6. The outside diameter of the bearing race is 21.989–22.002 mm (0.8657–0.8662 in.).
7. The diameter of the bearing housing in the pump body should be 21.072–21.993 mm (0.8296–0.8659 in.).
8. The inside diameter of the bearing race should be 9.990–10.002 mm (0.3933–0.3938 in.).
9. Check the diameters of the pump shafts, 9.985–10.000 mm (0.3931–0.3937 in.).
10. Replace any parts which are not within the limits given.

Installation



1. Soak the oil pump in clean motor oil before installation.
2. Reverse the removal procedure, using new gaskets where applicable. When installing the timing sprocket assembly, refer to the "Valve Timing" section of "Engine and Transmission" to ensure that this is set correctly.

Oil Pressure Relief Valve

The relief valve is mounted on the oil pipe inside the crankcase on most models, or in the oil pan casting on models with a cartridge type oil filter.

This is a maintenance-free item, which must be replaced if it fails to function properly.

The relief valve opens whenever oil pressure exceeds the prescribed rating. When the valve opens, the pressure drops and the valve will stay open until pressure returns to normal.

The standard maximum pressure is 35.6–42.7 psi (2.5–3.0 kg/sq cm) for the 700cc engine, and 54.0–60.0 psi (3.9–4.2 kg/sq cm) for all 750 and 850cc models.

Disassembly of the relief valve must not be undertaken as it will affect the operation of the valve.

Oil Breather

Situated on the top of the crankcase between the cylinders, the oil breather box contains a diaphragm held closed by a spring. When the oil pressure relief valve opens, the excess pressure is discharged into the breather box. The oil mist is separated out: the oil returning to the crankcase, and air released into the atmosphere.

If the machine has not been used for some time, it is possible for deposits to form on and eventually clog the breather diaphragm. This will result in oil leakages due to the lack of venting. If this is noted, remove the fuel tank, disconnect all of the lines running to the breather, remove the securing bolt, and remove the breather.

By means of a stiff, thin, rod inserted into the main breather box tube, check that the diaphragm is free to move. If it is not, soak the box in a suitable solvent until the diaphragm can be freed.

Oil Pressure Solenoid

A crankcase-mounted solenoid is fitted which is connected to a warning light to indicate whether proper oil pressure is being maintained.

The warning light should go out as soon as the engine is started. If it does not, or if it comes on while running, stop the engine immediately, and determine the cause of oil pressure failure.

Oil Lines

External oil lines which feed the cylinder heads should be checked for cracks or abrasion damage periodically, and replaced if even minor damage is noted.

Breather lines are rubber and should be inspected for dry-rotting or cracking, and replaced as necessary.

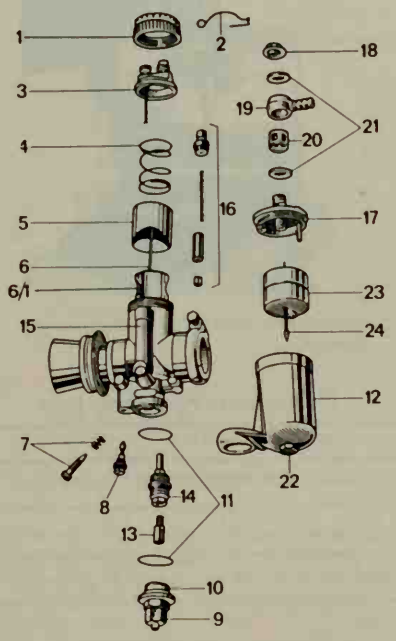
Fuel System

The V700 uses a carburetor with a separate float bowl. All other models are equipped with Dell'Orto concentric float bowl carburetors featuring an accelerator pump, except for a very few 1973 or 1974 machines which were fitted with Amal Concentric carburetors.

Dell'Orto Carburetors

NOTE: *Numbers in the text refer to parts labelled in the exploded views of the carburetors.*



V700

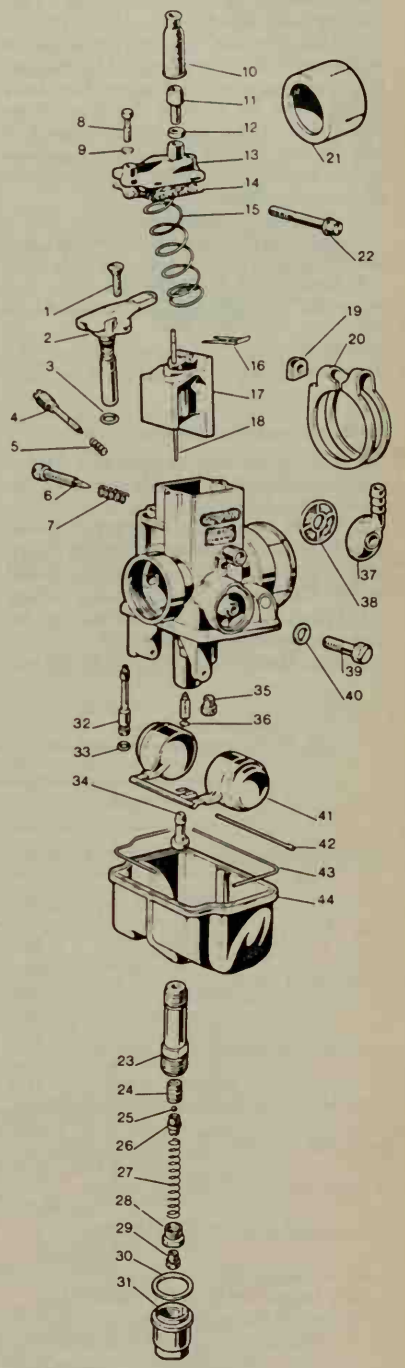
Removal

1. After ensuring that the fuel petcocks are "off," remove the float bowl drain plug (22) to drain off the gas, catching it in a suitable container.
2. Remove the spring clip (2) from the carburetor cap ring nut (1), then unscrew the nut and remove the cap (3), and the spring, slide, and needle (4, 5, 6) as an assembly.
3. Disconnect the fuel feed line from the float bowl. Alternately, remove the banjo bolt (18), banjo (19), and filter screen (20) from the float bowl.
4. Unscrew the choke assembly (16).
5. Loosen the manifold clamp screw and remove the carburetor.

Disassembly

1. If disassembly of the throttle slide assembly is desired, compress the slide spring to disengage the throttle stop rod from the slide. The components can then be separated.
2. Remove the float bowl banjo if this has not yet been done, removing the filter screen, then the float bowl cap (17), float and needle (23, 24).
3. Remove the float bowl securing bolt (10), venturi block (6/1), pilot air screw and spring (7), pilot jet (8), and main jet (13), and jet holder and needle jet (14).

Carburetor components (V700). See text for references



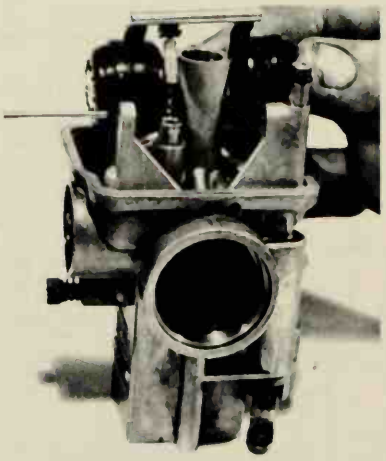
Assembly and Installation

1. Use new gaskets and o-rings.
2. When installing the pilot air screw, turn it in until it bottoms lightly, then back it out 1–1½ turns.
3. When fitting the carburetor, be sure it is positioned vertically. Check throttle action and check for fuel leaks before starting the machine.

750 AND 850 MODELS

Removal

1. Removal of the gask tank is recommended to facilitate carburetor removal. Remove the air cleaner, if fitted.
2. Ensuring that the fuel petcocks are "off," disconnect the fuel feed line at the carburetor.
3. Remove the two screws (8) which secure the carburetor cap (13) and pull out the throttle slide assembly.
4. If a cable-operated choke is fitted, remove the screw (1) and pull out the choke assembly carefully.
5. Loosen the manifold clamp screw (22) and pull off the carburetor, handling it carefully, as there is gas in the float bowl.



Carburetor components (All except V700). See text for references

Disassembly

1. Disassembly of the throttle slide components is easily accomplished by removing the return spring from its seat on the slide and disengaging the cable. To remove the needle, push the clip out with a screwdriver. Note needle clip position before this is done.
2. On models with a lever-operated choke, remove the securing screw (1) and carefully pull out the choke assembly (2, 3).
3. Remove the fuel feed banjo screw (39), the banjo (37), and filter screen (38).
4. Remove the float bowl nut (31).
5. Unscrew and remove the main jet and accelerator pump assembly (23–29). It is not necessary to disassemble these components for routine cleaning. If replacement of the main jet is desired, it may be unscrewed from the accelerator pump assembly without disturbing the other components.
6. Remove the float bowl (44).
7. Pull out the float pivot pin (42), and lift off the float (41) and float needle (36).
8. Remove the needle jet (34). Unscrew the pilot jet (35) and the starter jet (32).
9. Remove the pilot screw (4) and the throttle stop screw (6) and their springs.

Assembly and Installation

1. The use of new gaskets and o-rings is recommended, although they may be reused if undamaged.
2. When installing the pilot screw, turn it in until it bottoms lightly, then back it out the number of turns indicated in the "Carburetor Specifications" chart.
3. When installing the carburetor, be sure it is positioned vertically.
4. The throttle slide consists of two parallel plates. This must be installed so that the smaller of the plates faces *away from* the engine.
5. Check throttle action and check for fuel leaks before starting the machine.

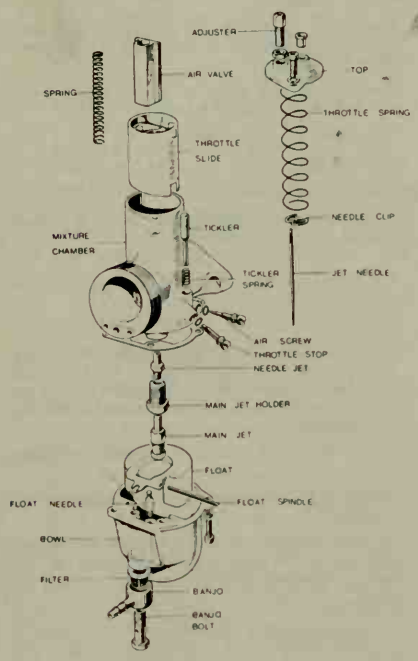
Removing the float assembly

Removing the main jet and accelerator pump assembly

Concentric Carburetors

A few late model machines may be fitted with Amal Concentric carburetors. Disassembly of the unit will be clarified by referring to the exploded view provided.

Petcocks and Fuel Lines



1. The electrovalve needs no maintenance. If it is operating correctly, there will be a distinct "click" when the ignition key is turned.
2. The manual petcock should be operated from time to time to check operation. If the "reserve" position has not been used for extended periods of time, it is possible that quantities of water may accumulate in the bottom of the gas tank. Disconnect the fuel line at the manual petcock to check operation in all three positions. When in the "Off" position, the petcock must stop fuel flow completely, or replacement is in order.
3. Both petcocks are equipped with a fuel filter screen. At extended intervals, they should be removed from the gas tank, and the filters washed in solvent to remove any trapped matter.

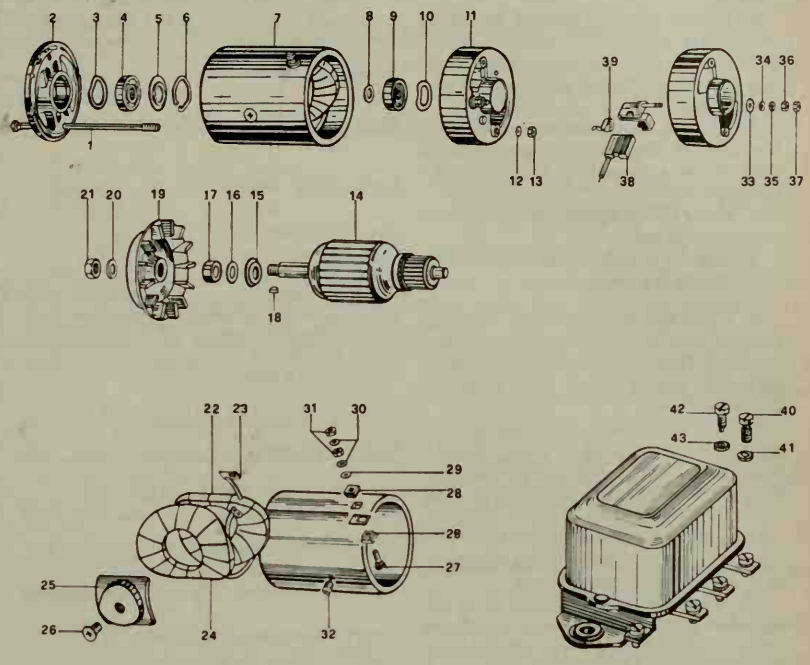
Electrical System



V700, V750, and V850 utilize a DC generator in conjunction with a mechanical voltage regulator for charging. The ignition system has a single contact point set with rotor and distributor cap.

750 Sport and 850T/T3 models are fitted with an alternator, rectifier, and regulator. The ignition system has two sets of points, and twin coils.

DC Charging System

GENERATOR

The models with DC generators come equipped with a Marelli DN 62 Type N generator which, at 2400 rpm, produces 300 watts at 12 volts. The unit is of the open construction type, has two poles, and operates in conjunction with a separate regulator unit. The rotor spins on two permanently lubricated ball bearings which are intended to be maintenance free items. The cover assembly is attached by means of two studs which pass through the unit. There are two terminals D+/51 (A) and DF (B), located on the commutator end of the housing which are used to connect the regulator wiring to the generator. The D+ terminal is connected to the positive brush and the DF terminal is connected to one end of the rotor assembly. When the generator is attached to the regulator, the D+ and DF terminals of both units must be connected.

Troubleshooting the Generating System

The following is the most direct approach to take in locating generating system difficulties:

1. The following items are indicators of a faulty generating system:

a. Failure of the generator light to go off.

b. Repeated or sudden battery discharging.

c. Excessive battery water evaporation indicating an overcharged state.

2. In testing the generating system do not commit the following mistakes which will result in damage to the system:

a. Do not reverse the generator polarity.

b. Do not short or ground any wires unless specifically instructed to do so.

c. Do not operate the engine while the generator output terminal is disconnected.

d. Always connect positive to positive and the negative to negative when connecting a charger or booster to the battery.

e. Keep the generator and regulator units connected.

3. Check for a faulty generator light in the following manner:

a. If the ignition is on and the light remains on, disconnect the generator leads at their terminals. If the light stays on, check for a short between these two leads.

b. If the generator light doesn't go on when the ignition switch is turned on, check the bulb; if satisfactory, check for a short between the two leads. If the light still doesn't come on, reverse the two leads. If the light still doesn't come on, check for an open circuit in the following manner:

(A) Connect the two leads of a voltmeter to ground and the DF generator terminal and check for a reading. Go on to the next step if a reading is obtained. No reading indicates an open circuit between the DF terminal and the battery. Correct this, then see if the light goes on when the ignition is turned on.

(B) Either connect or disconnect both generator leads, turn the ignition switch on, and momentarily ground the D+ terminal lead only. If the light does not come on, check for a burned out bulb, blown fuse, faulty bulb socket, or an open condition between the D+ terminal and the ignition switch. Remove the ground from the D+ terminal if the light comes on and, with both terminals connected, ground the generator.

(C) If the light still hasn't come on, check for open circuits between the wiring harness and the No. 1 terminal, generator brushes, slip rings, and field windings.

(D) If the light came on in the first step and there was a voltmeter reading, replace the regulator.

(E) Consult the next section if the light stays on when the motor is running.

4. Locate the reason for an undercharged battery in the following manner:

a. Make sure the reason the battery keeps going down is not because the accessories have been left on without the engine running.

b. Check the drive belt for proper tension.

c. Check the battery for shorting with a voltmeter or hydrometer indicated by one or more dead cells.

d. Inspect all writing for loose or poor connections.

e. Connect the leads of a voltmeter from ground to the generator "BAT" terminal, then the no. 1 terminal, then the no. 2 terminal. No reading indicates an open condition between the battery and the voltmeter connection.

DC Generator Troubleshooting

Possible Causes	*Remedy*
Generator does not charge battery	
Blown fuse on generator or battery (+) terminal	Check and, if necessary, replace fuse. Fuse contact could also be defective or fuse could be improperly housed in its seat
Break in charge circuit	Locate break and repair it. Breaks are generally due to loose or oxidated terminals
Slack generator belt	Adjust belt to correct tension
Faulty battery	Check battery
Generator does not charge battery	
Defective contact of brushes with commutator, dirty commutator, brushes not freely sliding in holders or worn out	Clean commutator, clean brush holders, or replace brushes
Grounded brush holder	Reset brush holder insulation and replace it if necessary
Grounded or broken rotor winding	Replace rotor
Short-circuited rotor	Clean carefully between rotor blades. Make sure that there are no welding drops on front face and especially on back side of commutator ring. If so, remove them. Failing to attain a good result, replace rotor.
Rotor unwelded from commutator	Renew welding if rotor does not show any other fault
Broken, short-circuited, or grounded field windings	Replace field coils unless grounding is spotted and eliminated
Generator lacks residual magnetism	Re-excite generator by connecting, for an instant, the (+) and (−) field winding terminals to (+) and (−) battery terminals
Faulty regulator	Replace
Generator is slow to start battery charge	
Faulty regulator unit	Replace
Partially short-circuited rotor	Replace rotor
Partially short-circuited field windings	Replace field windings
Grounded field windings	Replace windings if grounding cannot be eliminated
Battery gets only partially charged	
Oxidation of regulator unit contacts	Clean regulator unit contacts
Loose or defective connections inside regulator unit	Check and make connections positive
Faulty battery	Check battery
Generator overcharges battery	
Faulty generator grounding	Re-establish connection
Excitation circuit and generator (+) in direct short circuit	Overhaul system and eliminate fault
Faulty regulator windings	Replace
Battery discharges over generator	
Faulty regulator unit	Replace
Generator tension is not constant and exceeds prescribed value	
Faulty regulator unit	Replace
Tension oscillates and is not constant	
Oxidation of regulator unit contacts	Clean regulator unit contacts
Regulator unit with altered air gaps, loose screws, etc.	Replace
Overheating of generator	
Short circuited rotor	Replace rotor
Regulator unit damaged or out of setting	Replace
Brushes wear out too quickly	
Offset commutator	Turn commutator and remove excess mica
Excessive pressure of brush holder springs	Take spring pressure down to correct load
Brushes of poor quality	Replace brushes and fit with original parts
Excessive sparking at commutator	
Break in rotor winding	Replace rotor
Rotor unwelded from commutator	Renew weldings if there is no other fault
Offset commutator	Turn commutator and remove excess mica
Loose brush holder springs	Replace springs or restore correct spring load
Worn out brushes	Replace brushes
Mica protruding from commutator bars	Remove excess mica

5. Check the generator in the following manner if the problem hasn't yet been discovered:

a. Disconnect the battery ground wire, connect an ammeter so the current will pass through it from the generator D+ terminal to the lead which was connected to the D+ terminal, and reconnect the battery ground wire.

b. Turn on all of the accessories and attach a carbon pile across the battery terminals. Operate the engine until the maximum current output is obtained.

c. If the generator is good, amperage output will be within 10 percent of its rated output. Go back and recheck the previous steps.

d. Ground the generator by inserting a screwdriver through the generator test hole if amperage isn't within 10 percent of its normal rating.

e. Recheck with a carbon pile as described above. If the reading is still not within 10 percent, the regulator must be replaced.

f. Recheck with a carbon pile and overhaul the generator if the reading still isn't within 10 percent of its rated amperage.

6. Locate the reason for an overcharged battery in the following manner:

a. Check the state of battery charge with a voltmeter or hydrometer.

b. Connect the leads of a voltmeter to ground and to the generator DF terminal to check for an open reading (zero). The voltage, in any case, should not exceed 12 volts at 0° F. Discrepancies in measurements taken in cold and hot conditions are to be expected.

7. If the above test proves that the circuit is good and excessive water evaporation still indicates an overcharged battery, separate the generator end frames and check the field windings for a shorted condition in the following manner:

a. Connect the leads of an ohmmeter from the brush lead clip to the end frame and then reverse the connections. The ohmmeter must be set on its lowest range scale.

b. If both readings are zero, check for a grounded brush lead. This is probably caused by a missing or damaged insulating washer or insulating screw sleeve.

c. If, after replacing the insulating elements, both readings are still zero, the regulator is defective and must be replaced.

DC Generator Troubleshooting (cont.)

Noisy generator operation

Rotor rubs against pole shoes	Make sure pole shoes are correctly secured to casing. Replace bearings

REGULATOR

These models use the Marelli IR 50 BA type regulator which is a three coil unit and is mounted to the frame. The unit is not repairable or adjustable and must be replaced if defective.

AC Charging System

The following applies to 750 Sport and 850T/T3 models which are fitted with an alternator.

ALTERNATOR

NOTE: *Disconnect all wires at the alternator before carrying out the following tests.*

1. The commutator slip-rings should be cleaned with a solvent to remove any carbon build-up. Minimum commutator diameter is 28.6 mm (1.13 in.).

2. Check the carbon brushes for wear. Both must make good contact with the commutator. Replace the brushes if wear seems excessive.

3. Check for continuity between the commutator slip-rings. If an ohmmeter is available, resistance should be 6.3 ohms. If there is no continuity, replace the rotor.

4. Check for continuity between the stator terminals. Resistance should be 0.5 ohms. If there is no continuity, or if resistance is infinite, replace the stator.

REGULATOR

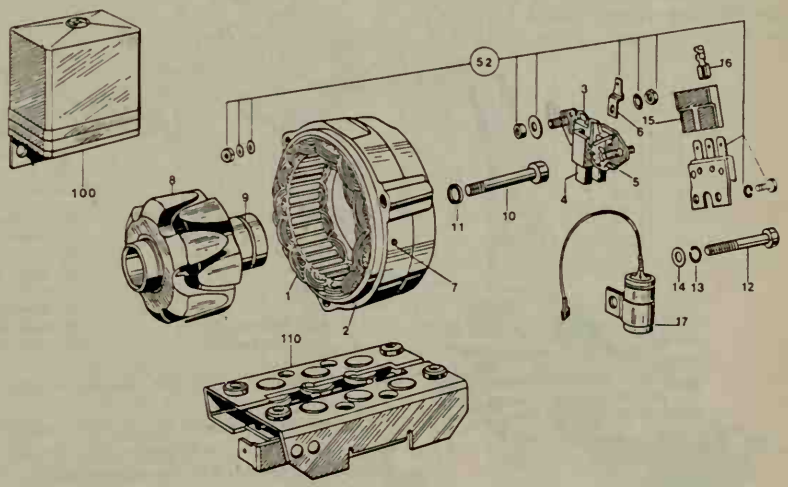
The regulator is located beneath the gas tank. The following specifications apply at 4500 rpm:

Test load: 13 A
Adjusting voltage: 13.9–14.8 V
Set load at nominal voltage: 330–360 W

RECTIFIER

The easiest and surest rectifier test is done by replacing the suspect unit with one known to be in working order.

Ignition System



1. Noise suppressor spark plug caps are fitted which have a resistance of 5,000 ohms. In the event of a misfire or lack of spark not attributable to other components, check the resistance of the cap(s). Replace them as a set if resistance is not close to the specification. Broken or cracked insulation inside the caps may also cause ignition problems, especially in wet weather.

2. Ignition coil resistance across the low tension terminals should be abont 3 ohms. Resistance between the high tension (spark plug) lead and one of the low tension terminals should be about 6,200 ohms.

If readings are not close to these specifications, replace the coil.

Electric Starter

V700, V750, V850, 850T/T3

These models use a starter motor with an integral solenoid. When the starter button is pushed, the current passes through the solenoid, which is an electromagnetic switch and the switch makes contact with the two high tension terminals visible on the rear of the solenoid. This allows current to flow from the battery to the starter motor which then begins to turn. At the same time, the movement of the solenoid switch referred to moves a lever which is attached to the starter motor gear, forcing the gear into engagement with the crankshaft ring gear.

750 SPORT

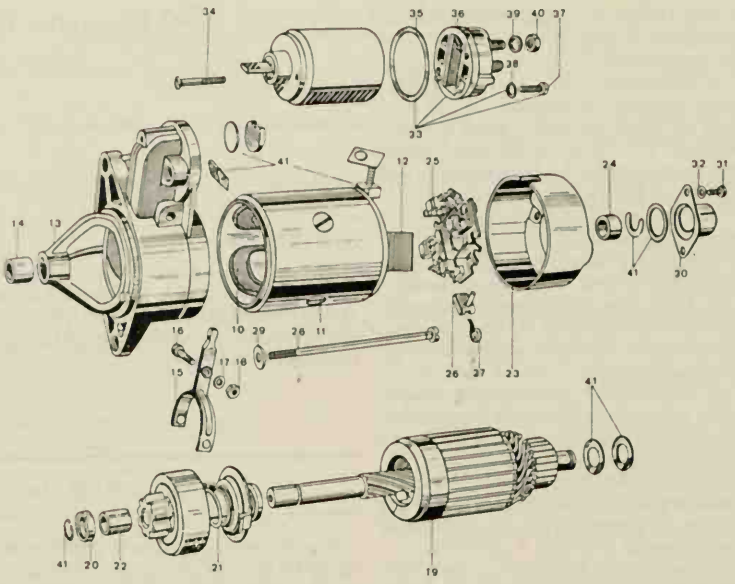
The operation of this starter motor is similar to that described above, except that the solenoid is not involved in engaging the starter motor gear. Instead, it merely allows current flow through the starter motor windings. When the starter turns, centrifugal force and a threaded armature shaft cause the starter motor gear to move along the armature shaft to engage the crankshaft ring gear.

TROUBLESHOOTING

The most common starter fault is due to wear of the armature bushings. This will cause the armature to contact the field coils, creating a short circuit.

This fault is especially common in models which use the 0.4 hp Bosch starter (750 Sport).

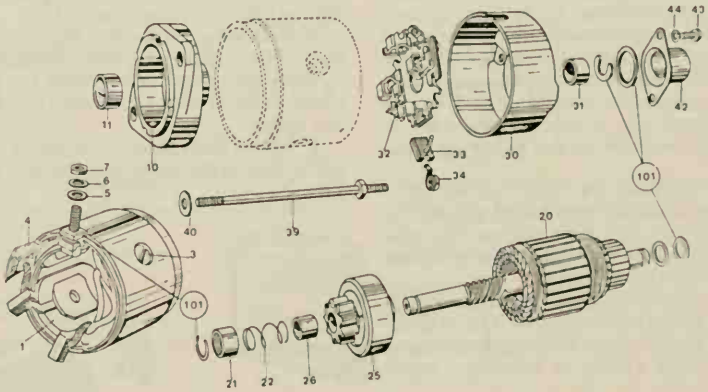
In this case, the starter will turn the engine over slowly or not at all and will show signs of overheating if repeated attempts at starting are made. When the starter button is pushed, the warning lights will dim indicating that the starter is drawing current.



This trouble can easily be checked by removing the starter. Check for play of the armature shaft. There should be none. If play is noticeable, the drive side bushing is worn.

On the starter found on models except the Sport, bushing replacement is simple since it is outboard of the starter gear.

On the Sport starter, it is necessary to remove the starter gear. This is accomplished by pushing down the sleeve on the drive end of the armature shaft, which will reveal a lock ring in a groove. Pry out the ring, and remove the sleeve, spring, and starter gear assembly. Remove the two through-studs and take off the drive side end plate complete with bushing.



At this point the starter should be handled carefully, since if the brush side armature shaft cap has been removed, it is possible for the armature to fall out of the starter body.

If the bushing is damaged, it can be purchased already installed in a new end plate. This is recommended. If the starter has been subjected to some stress, it is possible that the end plate itself is cracked.

Chassis

Wheel Removal

FRONT DRUM BRAKE

1. Support the front wheel several inches off the ground.
2. Disconnect the brake cable(s) from the lever(s) on the brake plate(s).
3. Remove the axle nut. Loosen the pinch bolts. Pull out the axle.
4. Installation is the reverse of removal. Be sure to engage the anchor studs on the brake plate with the slot(s) in the slider(s).

REAR DRUM BRAKE

1. Flip up the rear fender section if hinged fender is fitted.
2. Disconnect the brake cable or rod from the lever on the rear brake plate.
3. Remove the axle nut. Loosen the swing arm axle pinch bolt. Remove the brake anchor nut and disengage the anchor from the brake plate.
4. Remove the axle. Move the wheel as far as possible to the left to disengage it from the drive box and remove the wheel, tilting the machine to the side if necessary.
5. Installation is the reverse of removal.

FRONT DISC BRAKE

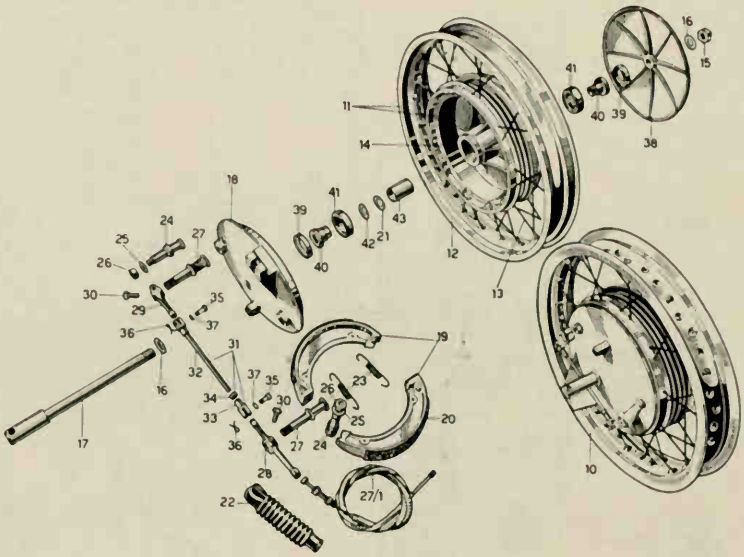
1. Support the front wheel off the ground.
2. On machines with a single disc, remove the axle nut, loosen the axle pinch bolts, and pull out the axle to remove the wheel.
3. On machines with a dual-disc, unbolt the right-side caliper from the fork slider. Remove the axle nut. Loosen the axle pinch bolts. Pull out the axle, noting

the position of any spacers, and remove the wheel.

4. Installation is the reverse of removal

REAR DISC BRAKE

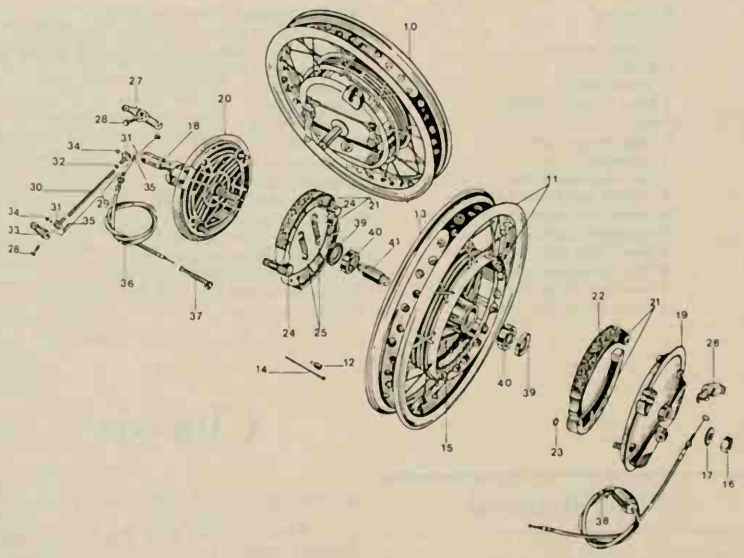
1. Remove the left exhaust pipe.
2. Remove the axle nut. Loosen the swing arm axle pinch bolt. Pull out the axle.
3. Disengage the caliper from the disc.
4. Remove the caliper from the pin on the swing arm and hang it from the motorcycle lifting handgrip.
5. Lean the machine to the right and remove the wheel.
6. Installation is the reverse of removal.



Wheels

DRUM BRAKES

1. To remove brake shoes, remove the pinch bolts which secure the brake lever(s) to the cam(s). Mark the position of the lever(s) on the cam(s) to facilitate assembly.
2. Remove the lever linkage. Tap the brake cam(s) out of the brake plate, collecting any dust seals which may be fitted. Pull the brake shoes apart to release the cam(s).
3. It is recommended that brake return springs over three years old be replaced as a matter of preventive maintenance.
4. Assembly is the reverse of the above. Grease the cam(s) before installation.



BRAKE LINKAGE

1. Twin-leading shoe brake plates are fitted with an adjustable rod which connects the two brake levers on the brake plate. The rod is adjusted at the factory, and further adjustment is not usually necessary. It is neither necessary nor recommended to disturb the rod adjustment when removing the brake levers from the plate. If the position of the main lever is marked on its cam before removal, the linkage can be reinstalled in the proper position with no trouble, since the secondary lever will only go on its cam one way.
2. If it is felt that the linkage is improperly adjusted, proceed as follows. On the Sport four-leading shoe brake, disconnect one of the brake cables while adjusting the opposite brake.
3. With the wheel mounted on the machine and properly secured, remove the clevis pin which joins the linkage rod to the main brake lever. Loosen the rod locknut.
4. Have an assistant apply the brake until the shoes just contact the drum. With your hand, push against the secondary lever until the shoe contacts the drum. The eye of the rod and the hole in the main lever should align at this point. If they do not, lengthen or shorten the rod by screwing it in or out until these holes line up.
5. Fit the pin. Tighten the rod locknut.

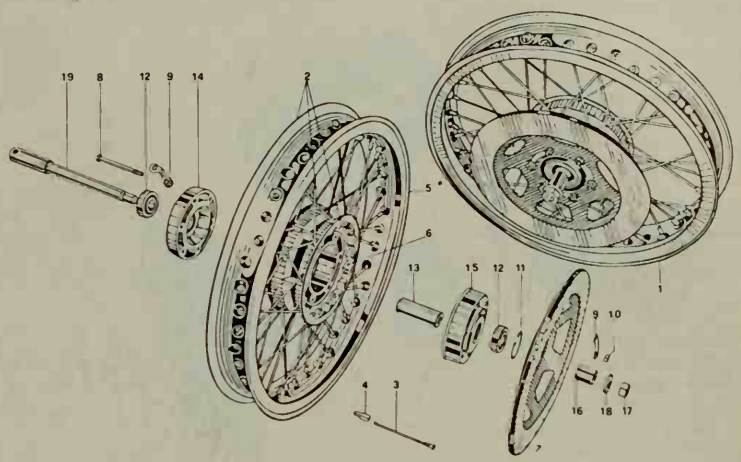
DISC BRAKES

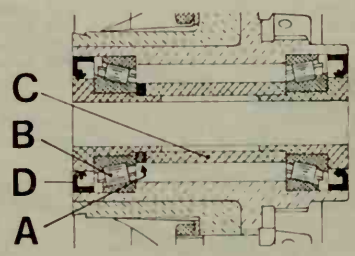
1. Check the brake disc for scoring or run-out. Maximum allowable lateral run-out is 0.2 mm (0.008 in.). Maximum allowable radial run-out is 0.06 mm (0.002 in.).
2. In the event of excessive disc run-out, check wheel bearing condition before replacing the disc.
3. The disc(s) can be removed from the wheel by removing the through-bolts. When refitting, torque through-bolts to 15.8–17.3 ft lbs.
4. For disc brake maintenance and caliper and master cylinder service, see below.



WHEEL BEARINGS

1. Models before 1974 use tapered roller rear wheel bearings. The bearings are held in place by the grease seals on either side of the hub, and can usually be removed by reaching through the hub with a punch to pop out the bearing. The outer bearing race will remain in the hub. New grease seals will probably be necessary.

There may be spacer shims in the rear wheel assembly, since the bearings are adjustable. To adjust the tapered roller bearings, proceed as follows:



a. Clean the bearings in solvent to remove the old grease, then oil lightly.

b. Install the bearing assembly using whatever shims are necessary placed between the left bearing and the spacer so that when the wheel is installed on the swing arm, and the rear axle nut is tightened to the proper torque of 100 ft lbs, wheel rotation becomes stiff. This is the zero bearing play position.

c. Disassemble the hub again and add a shim of 0.10 mm (0.0039 in.) thickness. Bearing adjustment is now correct. The wheel should have an axial play of 0.05 mm (0.002 in.) with ungreased bearings.

d. Disassemble and pack the bearings.

2. Front wheels and late model rear wheels are fitted with common ball bearings. On disc brake wheels the bearings will come away with the flanges after unbolting the brake disc(s). It is therefore not necessary to remove the bearings for inspection or repacking.

fluid which has been placed in a container. Remove the master cylinder cap and diaphragm.

3. Apply the brake, then loosen the bleed nipple. Apply the brake lever several times as the old fluid is expelled. Do not allow the master cylinder to empty. Add the new fluid as needed to maintain fluid level. Continue pumping the brake lever until new fluid begins to be expelled from the hose.

4. Tighten the bleed nipple, top up the master cylinder, and bleed the brake system in the usual manner.

BLEEDING

1. Bleeding should be accomplished after flushing, or if the brake lever feels spongy with an accompanying loss of braking power.

2. On integral brake systems, where two calipers are fed by one master cylinder, the caliper farthest from the master cylinder should be bled first.

3. Remove the rubber cap from the bleed nipple on the caliper and attach a suitably sized length of transparent plastic hose. Put a couple of inches of new brake fluid in a container and immerse the free end of the hose in it.

4. Apply the brake. Loosen the bleed nipple and the brake lever will be pulled to the end of its stroke. Observe the fluid discharged when this is done. Allow the lever to return *slowly* to its normal position. Wait several seconds before reapplying the brake. Continue the operation until the fluid being discharged from the plastic hose is free of air bubbles. Apply the brake lever, then tighten the bleed nipple and check brake operation before riding.

5. The fluid level in the master cylinder must be kept up during the bleeding operation. After the operation is complete, top up the reservoir to the marked line.

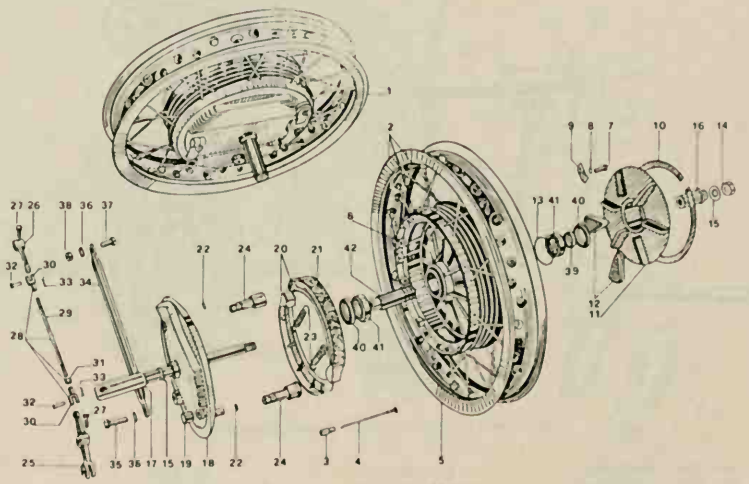
NOTE: *The front wheel should point straight ahead while bleeding front calipers.*

MASTER CYLINDER

1. The master cylinder should not be disassembled unless defective operation has been traced to it. Fluid leaking from the lever side of the master cylinder necessitates replacement of the piston seals.

2. Drain the fluid from the reservoir. Disconnect the fluid line at the master cylinder, cleaning off any dirt before disconnecting. Cover the open end of the feed line with a small plastic bag or the like to prevent the entry of foreign matter.

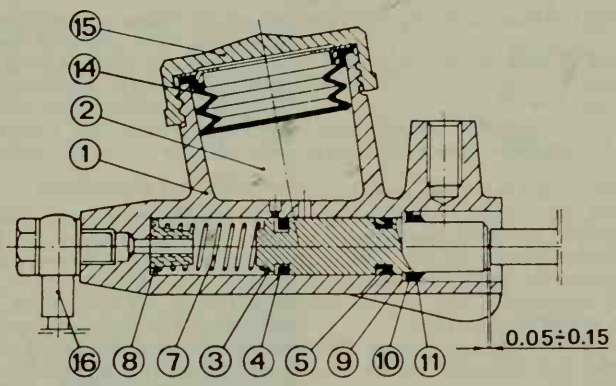
3. Remove the brake lever. Remove the master cylinder from the handlebar.



4. Special tool No. 14926400 is inserted into the feed line side of the master cylinder and used to push out the piston assembly. This must be done carefully to avoid scoring the cylinder walls. Remove the spring and guide bush from the cylinder.

5. To disassemble the piston, remove the lock ring, seal, and washer.

6. Carefully clean the piston components and master cylinder body in clean brake fluid.



CAUTION: *Do not use solvents or anything else to clean these components.*

7. Maximum allowable master cylinder passage diameter is 15.92 mm (0.621 in.). Minimum allowable piston diameter is 15.83 mm (0.617 in.).

Installing the piston seal with the special tool for the left-side seal

8. The seals on either end of the piston are fitted into grooves and require special tools to act as bushes so that they can be installed without damage. If the master cylinder leaks on the lever side, these seals must be replaced, but if they appear to be in good condition, and the cylinder does not leak, they should not be disturbed unless new seals and the proper tools are at hand. Tool No. 14926500 is used to install the right side seal, and Tool No. 14926600 for the left.

9. Lubricate all of the piston components, including the seals, in clean, new brake fluid. Install the washer, seal, and lockring on the piston.

10. Fit the spring and guide bush.

11. Install the piston assembly in the caliper pushing it in carefully to avoid damage to the bore or seals.

12. Use special tool No. 14926700 to press home the lockring until it is fully seated.

13. The remainder of the procedure is the reverse of removal. Check the clearance between the end of the piston and the brake lever (0.05–0.15 mm/0.002–0.006 in.) and adjust if necessary. Bleed the system. Check operation of the brakes before riding the motorcycle.

CALIPER

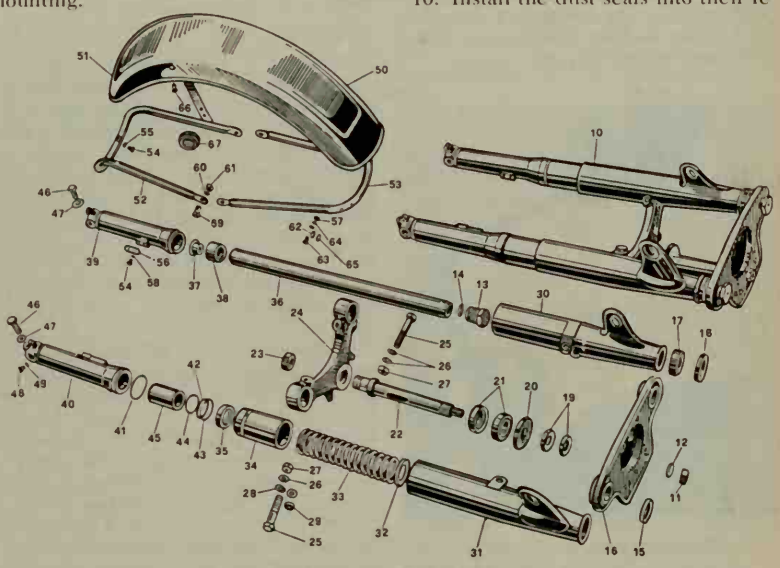
1. Disconnect and plug the brake line at the caliper.

2. Remove the caliper from its mounting.

3. Remove the tapered pin, spring, pad pins and pads.

4. Remove the bolts and separate the caliper halves. Remove the dust seals.

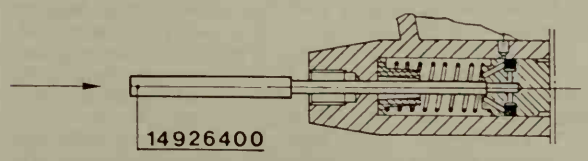
5. Apply compressed air to the fluid passage so that the piston is expelled from the caliper half. If the piston cannot be removed in this manner, the caliper must be replaced.



6. After removal of the pistons from the caliper halves, remove the fluid seals using a needle or the like, and taking extreme care not to score the caliper wall.

7. Clean all components in new, clean brake fluid.

8. Check the condition of the pistons and the caliper walls. Maximum allowable diameter of the caliper housing is 38.071 mm (1.485 in.), and minimum piston diameter is 37.930 mm (1.479 in.).



9. Use new seals for assembly, and coat these seals with new, clean brake fluid. Install the piston seal carefully into its groove. Lightly lubricate the pistons with brake fluid and press them into their calipers using hand pressure only.

2. Remove the instrument panel mounting screws, disconnect the electrical cables and the speedometer drive, then remove the instrument panel.

Removing the upper triple clamp

Steering stem locknuts

3. Remove the speedometer from the instrument panel.

4. Remove the nut and fork filler caps from the top triple clamp then pull the clamp using an appropriate wrench and tool No. 60910500 or a suitable substitute puller.

5. Remove the steering stem lock-ring (B) and lock-cap (A) from the top of the steering stem.

6. Remove the pinch bolts which secure the bottom triple clamp to the fork tubes.

7. Either drain the forks now by removing the drain plugs or pull out the tube and slider assemblies and then invert and drain the oil.

8. Remove the spring housings and springs as an assembly, then remove the headlight bracket bottom plate.

9. Remove the spring housings, then remove the seal ring and rubber ring from the housings.

10. Remove the circlip and adjusting washer, then remove the fork bottom cover and bushing.

11. Remove the bottom slider bushing lock-ring, then extract the bushing.

12. Remove the nut which secures the steering stem, from the bottom of the lower triple clamp, then remove the stem.

Inspection

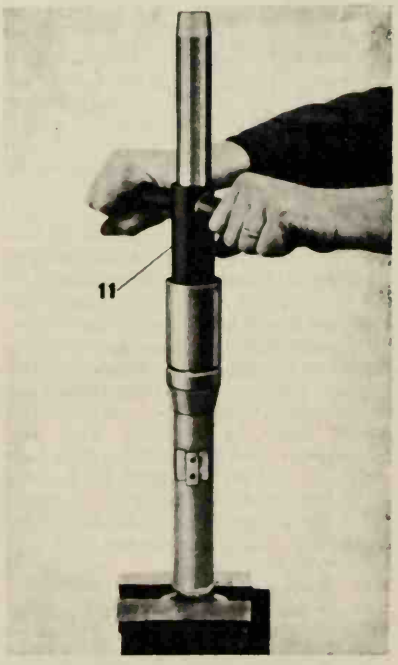
1. Using a micrometer or calipers, check the diameter of the tubes at the chromed portion, which must extend 120 mm (4.722 in.), and replace them if worn past their serviceable limit of 34.720–34.695 mm (1.3669–1.3659 in.). Using feeler gauges, check the clearance between the tubes and bushings and replace them if worn past their serviceable limit of 0.040–0.015 mm (0.0015–0.0041 in.) at the top bushing, and 0.020–0.044 mm (0.0007–0.0017 in.) at the bottom bushing.

2. Inspect the top bushings for signs of wear, damage, or scoring which would interfere with the proper operation of the forks, or which could damage the fork tubes, and replace them as necessary. Using inside and outside micrometers, measure the bushings and replace them if worn past their serviceable limits of 34.760–34.800 mm (1.3685–1.370 in.) for the inside diameter, and 40.010–39.971 mm (1.5751–1.5735 in.) for the outside diameter.

3. Inspect the bottom bushings. Their values are 34.700–34.739 mm (1.3661–1.3676 in.) for the inside diameter, and 39.950–39.911 mm (1.5728–1.5712 in.) for the outside diameter.

4. Inspect the fork bottom covers for damage or scoring of their inner surfaces and replace them as necessary. Using an inside micrometer, measure the inside diameter of the cover, then use feeler gauges to measure the clearances between the cover and the top and bottom bushings, and replace the components if worn past their serviceable limits. The inside diameter of the cover should be 40.010–40.050 mm (1.5751–1.5767 in.). The clearance between the cover and the top bushing should be 0–0.079 mm (0–0.10031 in.), and the clearance between the cover and the bottom bushing should be 0.099–0.100 mm (0.0038–0.0039 in.).

5. Inspect the fork springs for signs of wear, fatigue, excessive tilt, or damage and replace them as necessary. A new spring should be 230 ± 15 mm (9.0551 in.), and should be replaced if collapsed more than 3%. With a load of 110 ± 4 lbs the spring should be 170 mm (6.6929 in.), and with a load of 231 ± 8 lbs, the spring should be 104 mm (4.0945 in.).



Assembly and Installations

1. Install the top and bottom fork cover bushings, then secure them with bushing lock-rings. Use new lock-rings if the old ones are distorted.

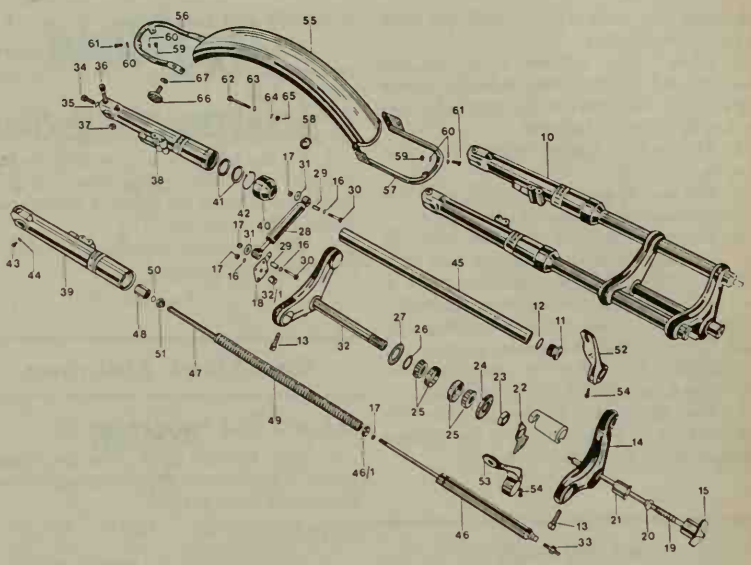
2. Install the fork tubes complete with the sliders, then position the adjusting washer in the top portion of the cover and install the circlip in the cover groove.

3. Place the fork cover gasket, cover, and spring housing in position.

4. Carefully press the seal ring into position, then secure the spring housing using Tool No. 12912600 (labeled "11" in the accompanying illustration) or a suitable substitute.

Installing a slider oil seal with the special tool

5. Slip the fork springs over the fork tubes and position them in the spring housing; then insert the fork tubes in the bottom triple clamp and headlight bracket using Tool No. 12909500 (labeled "4" in the accompanying illustration), or a suitable substitute, to position them.



6. Install the pinch bolts and secure the headlight bracket, then secure the steering stem to the bottom triple clamp with its nut.

7. Pack the steering head bearings with fresh grease and install them in the frame neck, then slip the steering stem and fork assembly into position so the stem seats fully inside the neck, and install the steering stem cap.

8. Position the steering stem lock-ring and adjust the steering play. The forks should pivot freely in the fork neck

750 SPORT, 850T/T3

Removal and Disassembly

1. Drain the fork oil. Support the front wheel off the ground. Remove the front wheel. Remove the brake caliper(s) from the forks, if disc brake. Remove the front fender.

2. Detach the electrical switches.

3. Remove the hydraulic steering damper unit, and engagement knob assembly.

4. Unbolt the headlight, disconnect the wiring, and remove the headlight unit. Remove the turn signal indicators.

5. Disconnect the tach and speedometer cables. Remove the instruments and warning light wiring and panel screws. Remove the panel.

6. Loosen the upper triple clamp pinch bolts. Remove the steering stem nut, the fork filler caps, and the upper triple clamp. Remove the headlight bracket. Disconnect wiring or control cables from the handlebars and remove the bars from the forks.

7. If removal of the forks only is desired, loosen the lower triple clamp pinch bolts, and pull down on the fork leg to remove it.

8. If removal of the steering stem and fork assembly is desired, remove the steering stem nut and take away the fork and steering assembly.

9. To disassemble the fork leg, secure the fork slider in a soft-face vise and remove the bolt at the very bottom of the slider. Pull the fork tube out of the slider, and remove the spring and damper assembly from the tube.

10. Remove the rod circlip. Remove the bottom cap and spring. Unscrew the rod from the damper.

11. Remove the dust seal from the top of the slider, followed by the circlip. Pry out the slider seals.

Inspection

1. Check that the chrome plating of the fork tubes is in good condition. Diameter of the fork tubes should be 34.72–34.74 mm (1.366–1.367 in.).

2. Tube-to-slider clearance is 0.010–0.085 mm (0.0004–0.0033 in.).

3. Inside diameter of the fork slider should be 34.75–34.79 mm (1.368–1.370 in.).

4. Fork spring free length is 418.5–423.5 mm (16.48–16.67 in.).

5. Fork dampers are sealed units and cannot be disassembled. Check that the units have equal damping rates. If one leaks or shows damage, replace both to ensure equal damping characteristics.

6. Check the damping characteristics of the steering damper. If it leaks or has lost its damping ability, replace it. The unit cannot be disassembled.

7. Check the condition of the steering stem bearings. Replace them if signs of wear or damage are evident. Rollers should be bright and smooth over their whole surface.

8. Check the condition of the outer races in the steering head. Races must be perfectly smooth and free of wear or ripples. If damaged the races must be replaced, and this is accomplished by removing them from the frame with a punch, and pressing the replacements straight in.

Assembly and Installation

1. The use of new seals and rubber parts is recommended.

2. Assemble the fork slider by carefully pressing in the new seals until they are seated then fitting the circlip. Lubri-

cate seal lips with ATF. Install the dust seals on the sliders.

3. Install the rubber ring on the damper rod. Install the locknut, screw the damper rod into the damper tube and secure it with the locknut.

4. Fit the fork spring, bottom cap and circlip assembly.

5. Fit the damper assembly into the fork tube and the tube into the slider.

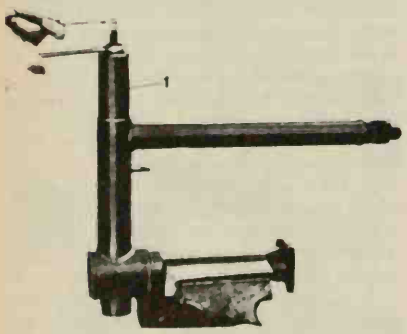
6. To assemble the steering stem, fit the dust cap, shim and bearing race onto the lower triple clamp steering stem in that order. Install the steering assembly on the frame, then the top bearing and dust cover. Install the steering stem nut and tighten it so that the steering stem will turn freely but without any play.

7. The remainder of the procedure is the reverse of removal. Add the proper amount of ATF to each fork leg.

Swing Arm

Removal and Disassembly

1. Remove the rear wheel. Remove the disc brake caliper, if necessary. Unbolt the shocks from the swing arm.



2. The swing arm can be removed complete with the drive box. If removal of the box is desired, drain the oil and unbolt it from the swing arm.

3. Loosen one of the clamps on the drive shaft rubber boot.

4. Remove the cap nuts from the pivot pins, if fitted (early models).

5. Loosen the swing arm pivot pin locknuts. Do not unscrew the locknuts. Just loosen them enough so the pins can be unscrewed. Try to keep the locknuts at the same place on the pins to preserve alignment upon assembly.

6. Unscrew the pivot pins. Pull off the swing arm assembly.

Removing the swing arm bearing race

7. Remove any grease seals or dust seals or spacers from either end of the swing arm. To remove the bearings, use special tool No. 12904700.

Assembly and Installation

1. Lubricate the bearings with bearing grease and install them. Press in the seals and spacers.

2. Install the swing, engaging the universal coupling with the shaft.

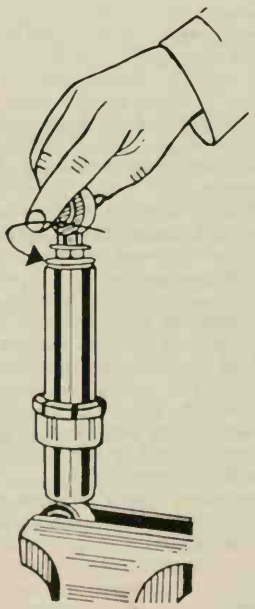
3. Fit the pivot pins, screwing them in equally until the swing arm can pivot freely but shows no signs of lateral play. Secure the locknuts.

4. The remainder of the procedure is the reverse of removal.

Rear Shock Absorbers

ALL MODELS EXCEPT SPORT

1. The shocks absorbers are sealed units. If leakage or other damage occurs, they must be replaced.



SPORT

1. Sport models are fitted with adjustable Koni® rear shock absorbers.

2. The standard factory setting is approximately 1½ turns from the minimum damping position. The maximum damping position is 2¼ turns.

3. If a change in damping rate is desired, remove the shocks from the motorcycle. Compress the spring, remove the collar, and remove the spring.

4. The rubber stopper should be moved down the damper shaft. Use a screwdriver or the like to pry it down off the top eyelet, if necessary, but take care not to damage or knick the damper shaft's chrome surface. Moving the rubber stopper down will expose a locknut against the top eyelet.

Adjusting the damping rate on Koni® shocks (Sport only)

5. Use the right size wrench to hold the locknut, then insert a rod into the eyelet and break it loose, then remove it. Remove the locknut. If the locknut resists removal, secure the damper shaft in a soft-faced vise by the threaded portion, then loosen the locknut as far as possible. Remove the damper shaft from the vise, and remove the locknut.

CAUTION: *Do not attempt to secure any part of the damper shaft which must enter the damper during adjustment or operation. The shaft is very easily knicked and the damper oil seal will be ruined.*

6. Remove the rubber stopper from the damper shaft. Refit the eyelet, and locknut, but do not tighten them excessively.

7. The adjuster mechanism is at the very bottom of the damper unit. Push the damper shaft in as far as possible without using excess pressure, then turn it a few degrees in either direction while maintaining a light pressure. The bottom of the shaft will engage the adjustment mechanism which can be felt when it happens.

8. Turn the damper shaft to the left until it stops. This is the minimum damping position. Turn the damper shaft to the right until the desired damping position is reached. Adjustments are made in increments on ¼ turn. Maximum damping position is 2¼ turns.

9. After adjustment, pull the damper shaft out an inch or so to disengage it from the adjustment mechanism. Refit the rubber stopper. Secure the eyelet and locknut.

10. Both shocks must have the same adjustment to provide satisfactory operation.

Maintenance

NOTE: *Common maintenance procedures are explained in detail in "General Information."*

Lubrication

ENGINE

Oil should be changed every 2500 miles under normal operating conditions. Change oil when engine is warm.

Use SAE 20/50 or SAE 30 "SE" if the average temperature is above 32° F., and SAE 10/30 or SAE 20 "SE" oil if below this.

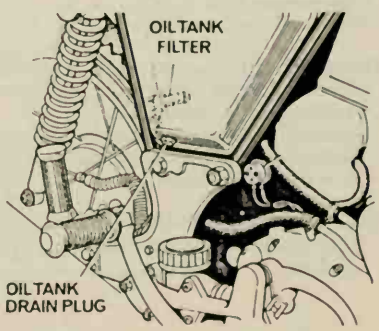
Checking Oil Level

1. Remove the seat, if necessary (as on Commandos) to gain access to the oil tank cap. Remove the cap.

2. Start the engine and let it run for a few moments until the sump has been scavenged and the oil in the tank is at its normal level as in operation. You can tell when the sump has been emptied, as the oil flow coming from the return line inside the oil tank will become intermittent and splutter somewhat.

3. Check the oil level. On Commando models, a dipstick is provided. The oil level should not exceed the "H" mark, or fall below the "L" mark.

Early Commando machines have an oil level tube adjacent to the oil tank. The oil level should be about half-way up the tube under operating conditions.



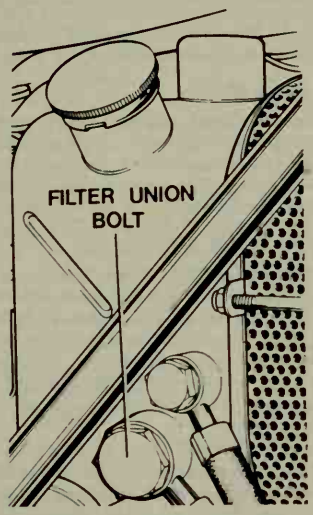
On all other models, gauge the oil level against the decal level lines on the side of the tank. Both maximum and minimum levels are marked.

Putting too much oil in will cause it to spill out of the overflow tube while in operation, while too little will cause an excess of heat to be built up in the remaining oil.

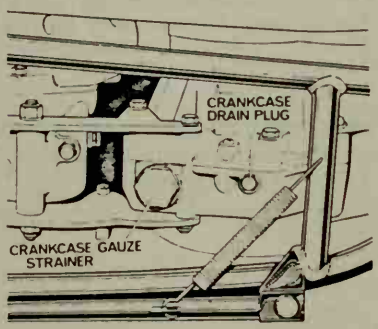
Changing Oil

1. Let the engine run until it is warm, then remove the seat (if necessary as on Commando models) and the right side cover (if fitted) to gain access to the tank filler cap and drain plug respectively.

2. Drain the warm oil out into a suitable receptacle. On the 1970 Roadster, the filter junction bolt must be removed to drain the oil tank.



3. Remove the crankcase sump drain plug and allow the sump to drain completely. There should only be a pint or so of oil in the sump.



On early 1973 Commando 750 models, only a small drain plug is fitted to the sump. On the 850 Commando, a large plug with filter is fitted along with a smaller magnetic plug. This small plug should be removed and cleaned when the oil is changed.

4. Clean the sump filter by removing the spring clip, taking out the washer, and pulling out the filter mesh.

5. Wash the filter thoroughly in a suitable solvent to remove all impurities

Roadster "S" tank filter bolt (1970)

Drain plugs (850 shown)

trapped in it. Also wash out the plug itself checking closely for metal particles.

6. Reassemble the filter in the plug and replace. Tighten the plug firmly.

Commando only:

7. Remove the oil feed line at the tank by loosening the securing nut. Remove the filter (held by a circlip) and clean it. Let the filter dry before refitting it.

On some 1973 Commando 750s, and on the 850 Commando, an automotive-type screw-on cartridge oil filter is fitted to the oil return line, and is located behind the gearbox. This filter should be removed and replaced about every other oil change.

Place a drip pan beneath the filter to catch any oil. Loosen the clamp and unscrew the filter, using a filter strap wrench if necessary.

To install, place a thin coat of oil around the O-ring of the new filter and screw it on hand-tight only. Tighten the clamp. Do not overtighten the clamp as this risks crushing the filter.

Pre-Commando:

For the other models, the factory did not recommend removing the filter on the oil feed pipe as just described for the Commando for fear of causing a leak at this spot by breaking the seal. Instead, the recommended procedure was to remove the oil tank completely and wash it out with kerosene or another suitable solvent.

a. Take off the metal oil pipe junction at the engine by removing the single fastening bolt.

b. Remove all other hose connections to the oil tank such as the crankcase breather, tank breather, etc.

c. Remove the three or four bolts which hold the oil tank to the frame (depending on the model) and remove the tank.

d. Flush the tank with the solvent several times to assure a complete cleansing job. Let the tank drain and dry thoroughly before refitting.

It is not necessary or recommended to perform this operation at every oil change. It should be done occasionally, though, and for certain if the engine has just been rebuilt.

Commando:

Although this should not be necessary for the Commando under normal conditions, the procedure is as follows:

a. Remove the seat and sidecovers from both sides of the machine.

b. Drain the oil as described above.

c. Take off the chain oiler pipe at the point where it enters the felt cartridge by compressing the spring clip and pulling the pipe away. Also remove the oil tank breather and crankcase breather pipes.

d. Unscrew the front and rear oil tank rubber mountings and remove the tank by lifting it to clear the bottom grommet and taking the bottom of the tank out of the frame first.

e. Reassembly is the reverse of the above procedure.

8. Occasionally check the filter in the oil pressure relief valve. To remove the valve, it may be necessary to take out the rocker oil feed banjo bolt immediately below it.

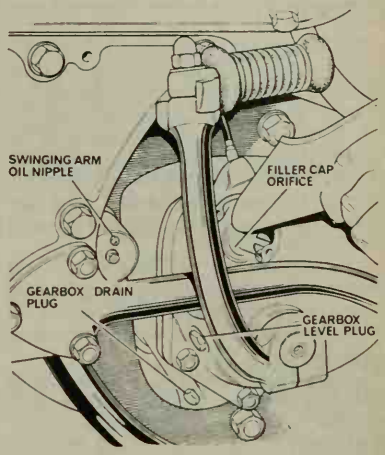
9. Refill the oil tank with the correct amount and grade of oil. Start the engine and let it run for three minutes. Then shut it off and let it sit for another two minutes. Recheck the oil level and fill it up as necessary.

GEARBOX

The change interval is 5000 miles. Oil should be warm when changing. Use SAE 90EP when average temperature is above 32° F and SAE 30 when it is below this.

Checking Oil

To check the level of oil in the gearbox, simply remove the oil level plug at the rear of the outer gearbox cover. The oil should begin to flow gently out.



Changing Oil

NOTE: *The oil should be warm when changing.*

1. Remove the clutch lever inspection cap on the outer cover.

2. Remove the drain plug at the bottom rear of the gearbox and allow the oil to drain out. Replace the drain plug and tighten it firmly, but avoid damaging the fiber washer.

3. Using a small funnel or other suitable device, add oil through the inspection cap. Add the oil slowly, as it is quite thick and must drain through a drilling in the inner cover to get to the gear compartment. When you have added the correct amount of oil (Commando: 1.2 pints; other models: 1 pint), let the oil sit for a minute to ensure that the level is equal in both the inner and outer compartments, then remove the level plug and check as before.

Gearbox plugs (all models)

4. Replace the level plug and the inspection cap.

PRIMARY CHAINCASE

The change interval is every 2500 miles. Change when engine is warm. Use the same type of oil being used in the engine.

Checking Oil Level

To check the primary chaincase oil level, remove the oil level plug at the middle, lower portion of the chaincase. The oil should seep gently out the level is correct.

Changing Chaincase Oil

1. Remove the left-side footpeg.

2. Place a long metal tray or suitable substitute beneath the chaincase, unscrew the central fixing bolt, or the screws around the chaincase cover as on some models, and pull off the chaincase cover just enough to break the joint and let the oil escape.

3. Let the cover sit for a moment until as much of the oil as possible has drained out, then remove the cover.

4. Wash out the cover with kerosene or another suitable solvent.

5. Replace the cover, remove the chain inspection cap, and add the correct amount and grade of oil with the aid of a small funnel. Check the oil level as before.

The primary chaincase for the Commando should be filled with 7 oz. of oil, while on the other models, the correct amount is 4.5 oz.

Never use any type of oil additive or a thicker grade of oil in the primary chaincase in an effort to slow or stop a leak, or for any other rason, as these may affect the operation of the clutch.

CAUTION: *Do not overfill the primary chaincase.*

FRONT FORKS

The oil should be changed every 5,000 miles (Commando), or 10,000 miles (pre-Commando) and refilled with the recommended grade in the correct amount.

1. Remove the small drain screw at the bottom of one fork leg, having a suitable receptacle ready to catch the oil. Push the bike off the center stand and work the forks up and down to completely drain all of the oil in the fork.

2. Allow the oil to drain for several minutes, then replace the drain screw, paying attention to the fiber washer to avoid damaging it. Drain the other fork leg in the same manner.

3. The large filler plug at the top of each fork leg must now be removed. If necessary for your bike, remove the handlebars for increased accessibility to the plugs.

With the bike off the center stand, remove *one* of the filler plugs.

CAUTION: *Do not remove both plugs with the bike off the center stand, or the forks will collapse.*

4. Push down on the front end so that the spring and damper rod rise out of the fork leg.

5. Using two wrenches, remove the filler plug from the damper rod.

6. Put the machine on the center stand so that the spring and damper rod retract into the fork leg, which they will do when the forks extend.

7. Pour the correct amount of oil into the fork leg. Atlas and Commando: 5 oz in each leg; Scramblers: 6.5 oz in each leg.

Oil must be added slowly. It takes time for the oil to seep past the spring and into the slider.

An alternate method to hasten filling is to cover the plug hole with the palm of one hand and then pump the forks up and down slightly.

8. After the oil has been added, push the machine off the stand again to expose the damper rod. Screw the filler plug onto the rod as far as possible, then lock the damper rod nut against it. A little thread locking compound can be used on the filler plug threads, as this will ensure that the damper rod does not come loose in operation.

9. Put the bike back on the center stand and screw the filler plug into the fork leg and tighten firmly. repeat the procedure with the remaining fork leg.

DRIVE CHAIN

The rear chain receives some lubrication from the oil tank by way of the tank breather tube. On Commandos, a felt regulator is incorporated into the tube. A lubricant developed specifically for motorcycle drive chains, however, should be used at regular intervals.

GREASE NIPPLES

On all drum brake models, grease nipples are fitted to the front and rear brake cam pivots. These should be lubricated every 5,000 miles with no more than one stroke of the grease gun to avoid getting grease inside the drum.

Most models also need lubrication of the rear brake pedal pivot and a fitting is provided for this purpose. Grease the pivot every 2,500 miles.

At the same interval, give a few shots of grease to the speedometer drive on the rear wheel.

On Commando models only, there is a nipple on the right side of the swing arm bush housing. This should be attended to every 5,000 miles. Fill it with SAE 140 oil.

To check the swing arm oil level, remove the spindle locating bolt at the top, center, of the swing arm pivot. Fill with oil until it begins to come out of the bolt hole.

CAUTION: *Be sure to use oil only; do not use grease.*

CONTACT BREAKER POINTS

Battery and Coil Ignition

Every 5,000 miles, when checking or replacing the contact breaker points, apply some grease to the breaker cam and to the pivot posts.

At the same time, apply a small amount of light oil to the centrifugal advance mechanism bob weights at their pivots. The advance mechanism is behind the breaker point plate.

In both cases, use the grease and oil very sparingly so you won't foul the points in the process.

Magneto Ignition

The cam ring in the Lucas K2F magneto has two holes drilled into it in which are fitted very small fiber wicks which hold and distribute oil. They are fed by much larger pieces of fiber beneath the cam ring. Every 3,000 miles, add oil sparingly to the cam ring face. Less often, the cam ring may be removed after first removing the center bolt, prying out the points and breaker plate, and very gently pulling out the cam plate. It must be pulled straight out by hand. Removing the cam ring will allow you to oil the fiber elements directly. Do it sparingly.

If the wicks in the ring are missing, as may happen after many miles, the ring can be lightly greased for the same purpose.

Also apply a drop of oil to the breaker point pivot post.

SPEEDOMETER AND TACHOMETER CABLES

The speedometer and tachometer cables should be removed, cleaned, inspected, and lubricated with grease periodically.

1. Disconnect the cables at the instruments or the drive box.

2. Withdraw the cables, leaving the outer housings in place.

3. Clean the cables thoroughly in kerosene, then inspect them for fraying.

4. Completely coat the cables with light-duty grease except for the 6 in. nearest the instruments.

5. Reinstall the cables as removed.

STEERING HEAD BEARINGS

Late Model Commando

If the machine does not have a large chrome hexagon nut at the top of the steering stem, it is the latest design. The fork bearings are therefore ball journal type, but pre-packed with grease at the factory which lasts for the life of the motorcycle. These bearings need neither lubrication nor adjustment of any kind.

All Other Models

Steering head bearing lubrication is necessary at intervals of about 20,000 miles. It is necessary to remove the fork legs and steering stem. Refer to "Chassis" for procedures.

REAR SHOCK ABSORBERS

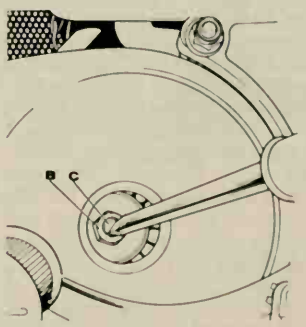
The Girling rear shock absorbers are maintenance-free sealed units and cannot be disassembled. If a shock absorber weeps oil, it must be replaced.

On some early machines, the upper part of the spring might be greased if it grates against the metal dust cover.

WHEEL BEARINGS

The maintenance interval for both front and rear wheel bearings is 10,000 miles, at which time they should be removed, cleaned, inspected, packed with the approved brand of grease, and replaced. Removal procedure is given in "Chassis."

Service Checks and Adjustments



CLUTCH

The procedure is essentially the same for all models.

1. Remove the clutch activating lever inspection cap on the gearbox and the clutch adjusting screw cap on the primary chaincase.

2. Run the clutch cable adjuster all the way down until there is slack in the cable.

3. Check the free-play of the clutch activating lever in the gearbox outer cover. There should be about ⅛ in. of free movement before the lever touches the clutch pushrod.

Clutch adjuster locknut (B) and adjuster (C)

4. Adjust, if necessary, by loosening the locknut on the adjusting screw in the center of the clutch hub.

5. Loosen the adjusting screw a few turns until you note the free-play in the gearbox lever.

6. Screw in the adjusting screw until it just touches the clutch pushrod.

7. On Commando models, back the adjusting screw off one full turn, then

tighten the locknut. On all other models, back the screw off ½ to ⅔ of a turn, then tighten the locknut.

8. Make sure that the activating lever has the required free-play. Take up the extra cable slack with the cable adjusters at the gearbox or the handlebar. There should be about ⅛ in. of free movement in the handlebar lever before it engages the clutch for pre-Commando models. This is measured between the hand lever and the lever holder. On the Commando, there should be between 3/16 in. and ¼ in. free movement between the cable outer casing and the adjuster.

BRAKE ADJUSTMENT

Commandos are fitted with either an hydraulic disc or a twin leading shoe drum-type brake at the front, and a single leading shoe at the rear on pre-1975 models. 1975 and later models have a disc at the rear wheel as well. Drum brakes are cable-operated on both wheels.

Other models usually had single leading shoe brakes front and rear, and the rear brake was rod-operated.

On all drum brakes, if the axle nut has been loosened, the brakes must be centralized in the drum before attempting adjustment. This is done by applying the brake hard with the axle nut loose, and then tightening the axle nut while keeping the brake applied. Then adjust the brake as outlined in the following sections.

Commando

FRONT, DRUM TYPE

1. Two adjusters are provided on the front brake cable: at the handlebar and at the drum itself. Usually, the adjuster at the drum is used to compensate for wear of the brake shoes.

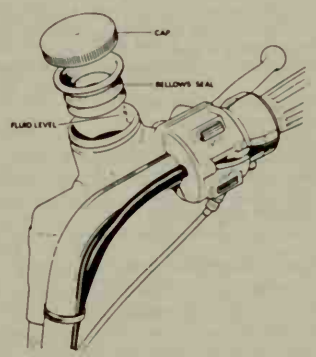
Adjust the brakes so that the shoes contact the drum after the handlebar brake lever has moved about 1 in. (measured at the tip of the lever).

2. The angle formed by the cable and the brake plate lever should not exceed 90° when the brake is fully applied. If it does, it is probable that the shoes are worn to the point of replacement.

3. The link rod for the twin leading shoe brake should be correctly set at the factory, and does not require periodic adjustment. If the linkage has been disassembled, or if new brake shoes are fitted, reset the linkage by first removing the top clevis pin. Then pull the handlebar lever until the brake shoe just contacts the drum. Have an assistant hold the handlebar brake lever in this position. Push down on the upper brake plate lever until the brake shoe contacts the drum. The clevis pin holes in the link rod and the lever should line up, if the brakes are correctly adjusted. If not, loosen the link rod locknut, and screw the rod in or out so that the holes line up. Tighten the locknut. Insert the clevis pin and fit the clip. Adjust the brake with the brake plate adjuster.

NOTE: *The pins should be checked periodically and replaced if they show signs of wear, or braking effectiveness will be reduced.*

4. The front brake is equipped with an



Adjusting tls brake rod

air scoop and an outlet, both of which are blocked off. The plates can be removed if desired, but the wire mesh screens must remain in place.

FRONT, DISC TYPE

1. The only required check besides pad wear is for fluid level. The fluid level should be ½ in. from the top of the reservoir. Add DOT 3 brake fluid only if topping up is necessary. Refit the diaphragm closed end down.

Disc brake fluid level should be ½ in. below the lip of the reservoir

Note that the fluid level may drop slightly as the pads wear. In this case it is not necessary to add additional fluid, since the level will rise when new pads are fitted.

2. Bleeding and flushing procedures for the hydraulic system are provided in "Chassis."

REAR, DRUM TYPE

1. A stop bolt is fitted so that the brake pedal can be positioned to suit rider preference. Adjust this before adjusting the brake. If the stop bolt is moved, check operation of the brake light switch.

2. When the rear brake is fully applied, the lever should not be past the 6 o'clock position. If it is, new linings are necessary. The brake is adjusted with the adjuster on the end of the cable. Allow about 1 in. of pedal travel before the linings contact the drum.

3. Adjust the brake light switch after adjusting the brake. Loosen the securing screws and move the switch up or down as necessary so that the brake light goes on as soon as the pedal is depressed.

4. Be sure that the brake pedal returns to rest against the stopper bolt, and not against the brake light switch, or the switch will be ruined. The switch plunger must *not* be fully compressed when the pedal is resting against its stop.

REAR, DISC TYPE

Check fluid level as outlined for "Front, Disc Type."

Pre-Commando

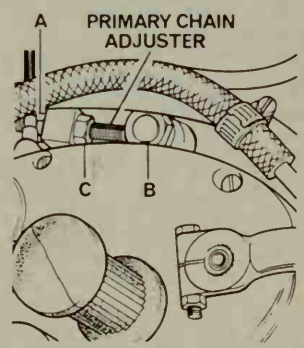
FRONT AND REAR

1. Adjust the front brake cable to allow about 1 in. of hand lever movement, measured at the tip of the lever, before the linings contact the drum.

The angle formed by the brake arm and the cable should not exceed 90° when the brake is fully applied, or the linings are probably worn to the point of replacement.

2. If the machine is equipped with a pedal stop for the rear brake pedal, this should be adjusted to the desired position first.

3. The rear brake, if rod-operated, must be adjusted with the motorcycle on its wheels and the weight of a rider on it. Allow about 1 in. of pedal movement before the linings contact the drum.



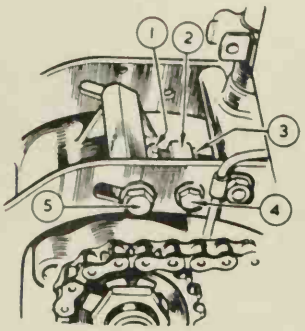
4. In all cases the wheels should be free to turn with no dragging from the brake linings.

PRIMARY DRIVE CHAIN

1974 and Earlier

On pre-Commando models, this adjustment should be made when the engine is at operating temperature.

1. Remove the primary chaincase inspection cap.



Primary chain adjuster locknuts (A&C) and locking bolt (B)

2. Loosen the large nut on the adjustment assembly on top of the gearbox. Also, loosen the nuts on the lower gearbox mounting stud.

3. On Scrambler models: screw down the adjuster bolt several turns. Pull down hard on the drive chain to take up the slack in the primary chain, then turn the adjuster bolt out until primary chain tension is correct. Tighten the lockbolt.

4. On other models: Back off the adjuster nut on the right several turns. Then tighten the nut on the left. The gearbox will pivot to the left to tighten the pri-

G15CS primary chain adjuster bolt (1), locknut (3), and gearbox lock bolt (5)

mary chain. Tighten the nut until the slack is completely gone, then back it off several turns and tighten the right nut until the correct chain slack is obtained. For Commandos this is ⅜ in. total up and down movement. For models with single-row chains, ½–¾ in.

5. Slowly rotate the chain and check the slack at several points. If the chain has a tight spot, the slack must be set to the correct specification at this point.

6. Tighten the large adjuster nut and the mounting stud nuts.

7. The final drive chain adjustment has been altered and must be checked.

1975 and Later

An automatic chain tensioner is fitted to the primary chain, so no adjustment is necessary.

FINAL DRIVE CHAIN

Before attempting adjustment, the chain must be clean and well lubricated. Check for tight spots and set slack at the tight spot, if any.

1. Loosen the rear axle nuts. Loosen the adjuster locknuts. Back off the rear brake adjuster (drum brake).

2. Pull down on the bottom chain run to ensure the wheel is aligned.

3. Turn each adjuster an equal amount until the chain is a bit looser than desired.

4. Check slack with the motorcycle on its wheels and a rider on it. Readjust, if necessary, until there is ¾ to 1 in. of slack (total up and down movement) measured in the middle of the bottom chain run.

5. Apply the rear drum brake, tighten the axle nuts and recheck chain slack. Tighten the adjuster locknuts.

6. Check that the brake is not dragging. On models with a rod-operated brake, the adjustment will have changed if the wheel was moved. Readjust the brake as necessary.

CAM CHAIN

1. Cam chain tension should be checked periodically. 1975 and later models are fitted with a plug on the timing case cover to allow the tension to be checked. On other models, the cover must be removed to check the tension.

2. Correct cam chain tension is ⅛–3/16 in. of total up-and-down movement measured in the middle of the upper chain run. Adjustment is by means of an adjustable slipper secured by two nuts.

Air Cleaner

1974 and Earlier

This is a paper element on most models, although it differs for each type of machine. Replace the filter paper every 5,000 miles or more often under dusty conditions.

On motorcycles like the Commando with its larger filter box, foam air cleaner elements can be fitted as a replacement. These are superior to paper filters and can be reused by washing them in solvent and oiling as per instructions. Follow the filter manufacturer's recommendations if this is done.

1975 and Later

A foam-type air cleaner is used on these machines. Under normal conditions the filter should be serviced every 3,000 miles by removing it from the machine, washing it in clean gasoline, and squeezing dry. Then soak the filter in motor oil, squeeze off the excess, and install.

Tune-Up

NOTE: *Common tune-up procedures are explained in detail in "General Information."*

Valve Adjustment

NOTE: *Valves must be adjusted when the engine is cold.*

1. Remove the gas tank after shutting off the fuel taps and disconnecting them at the tank. On some models, the seat must be removed first.
2. Remove the spark plugs, the two exhaust rocker covers, and the intake rocker cover.
3. Turn the engine over with the kick-starter until the left-side intake valve is fully open (the rocker arm will be depressed). The right intake valve will be closed at this point. Check the clearance at the right intake valve with a feeler gauge. It should be 0.006 in. for all models except Combat-equipped Commandos which are set at 0.008 in.

Adjusting the valves

The feeler gauge blade will be a slight drag fit in a correctly adjusted valve.

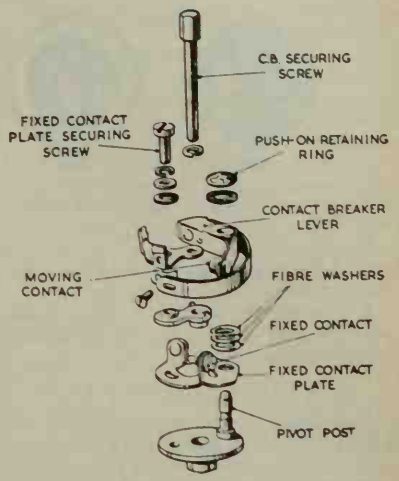
4. Adjust, if necessary, by loosening the locknut and turning down the adjuster until the feeler gauge blade can be pulled through with a slight drag on it.
5. Hold the adjuster in position and tighten the locknut. Recheck the gap after tightening.
6. Turn the engine over until the right intake valve is depressed, then adjust the left intake valve.
7. Repeat the procedure with the exhaust valves. Proper exhaust valve clearance for all standard engines is 0.008 in. Combat engines are set at 0.010 in.

Contact Breaker Points

MAGNETO IGNITION

The contact breaker points are located beneath the magneto cover on the left-side of the machine.

Removal



1. Loosen the kill-button wire knurled nut at the magneto. This is attached to the post in the center of the magneto cover.
2. Unscrew the cover and place it aside.
3. Loosen the central hex-head securing screw until it is clear of its threads but is still in the center of the contact breaker. It can be used to "break" the points off their tapered shaft by gently levering sideways with the fingers.
4. When the points have been taken off the shaft, remove them completely.

Installation

Installation is the reverse of the removal procedure. Clean the new points with a non-oily solvent to remove the preservative coating. Do not forget to replace the fiber washers on the pivot post. Refer to the illustration for correct position of various parts. Also, apply a drop of oil to the post for lubrication. Note that the points assembly has a key which must fit in its slot. Set the gap upon installation. The ignition timing need not be readjusted.

Gap Adjustment

1. Turn the engine over slowly until the points are fully open. This should be done with care. The points will be open at two positions on the cam ring. These points can be determined by looking at the cam ring itself. There are two "thick" areas. The points will be open when the contact breaker heel passes over these points which are about 6 o'clock and 12 o'clock.

Magneto breaker points assembly

2. Loosen the fixed contact plate securing screw, then use a screwdriver to move the fixed contact plate to the correct gap. Check the gap with the appropriate feeler gauge. It should be 0.012–0.015 in.
3. Tighten the fixed contact plate securing screw and recheck the gap.
4. Check that the gap is the same at both open positions on the cam ring. If it is not, set the gap so that it is within the given specification at both open positions.

CAPACITOR IGNITION

Capacitor ignition systems (or battery and coil ignition) are found on 1967 models as well as on Commandos. The earliest machines equipped with this system had the ignition points located in a canister behind the cylinder barrels and attached to the timing case. The first machines utilized dual points with the condensers mounted on the breaker plate. This set-up was soon replaced with yet another system: Lucas 6CA dual points, individually mounted on the breaker plate, the condensers being remotely positioned. The points on this later system allow each cylinder to be timed separately. This system was used on Commando models also up to engine No. 131257, when the points were relocated to the timing case. Aside from the new location, the points assembly is the same.

Commando 750s (1973) and Commando 850s use another type of breaker point assembly, the Lucas 10CA.

Early 1967 Models

REMOVAL

1. Remove the ignition point cover.
2. If desired, the points assembly may be removed as a unit to reveal the automatic timing advance mechanism. Disconnect the two wires from the snap connectors; remove the two screws which secure the breaker plate and remove the plate.
3. If replacement of the points only is desired, remove the two wires from the snap connectors, release the nut which holds the spring of each breaker point to

Early battery-and-coil breaker points and advance mechanism

its condenser, being careful of the insulating washers and their positions.

4. Remove the pillar nut which holds each breaker point onto the plate and take away the points.

Installation

Installation is the reverse of the removal procedure. Clean the new points with a solvent to remove the preservative coating. Be sure that all insulating washers are in their proper positions. Apply a drop of oil to the pivot posts.

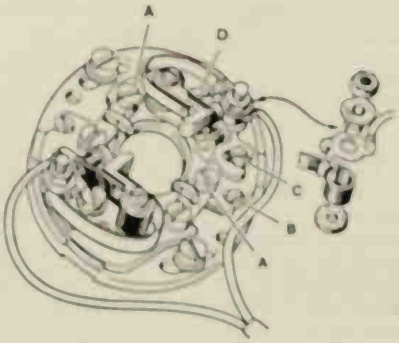
NOTE: *When refitting the contact breakers, assure that the wires are connected correctly. The yellow-black wire attached to the top contact breaker goes to the coil mounted on the left rear frame down tube. Also, the high tension lead from this coil goes to the drive side cylinder.*

When refitting the contact breaker cover, be sure that the two insulated strips for each condenser are in position.

Gap Adjustment

1. Turn the engine over until one of the breaker points is fully open.
2. Loosen the pillar nut which secures the breaker point fixed plate.
3. Use a screwdriver to adjust the gap by prying between the fixed plate and the contact breaker housing.
4. Using a feeler gauge, set the gap for each breaker point at 0.014–0.016 in.
5. Tighten the pillar nut and recheck the gap.

Late 1967 Models and Commando 750 to Engine No. 131257



These models utilize the Lucas 6CA points assembly, located behind the cylinders.

Removal

1. Remove the points cover.
2. If desired, the breaker points assembly may be removed as a unit to reveal the automatic timing advance mechanism by removing the two large screws which secure the breaker assembly plate.
3. To remove the points themselves, remove the hexagon nut which secures the wire and the contact breaker spring. Be especially careful of the plastic insulator sleeve and the fiber washer.
4. Remove the locking screw (D) and take off the breaker.

Installation

Installation is the reverse of the removal procedure. Ensure that the insulating washers and insulator sleeve are correctly positioned. Smear the pivot post with a bit of grease before refitting. Clean new points with a solvent to remove the preservative coating. When fitting the point cover, be sure it is seated on the rubber washer.

6CA points assembly

Gap Adjustment

1. Turn the engine over until the slash mark on the point cam aligns with the nylon heel of one of the breaker points.
2. Check the gap with the appropriate feeler gauge. It should be 0.014–0.016 in.
3. If adjustment is necessary, loosen the locking screw (D) and turn the eccentric screw (C) until the proper gap is attained.
4. Tighten the locking screw and recheck the gap.
5. Repeat the procedure for the remaining point set.

Commando 750 From Engine No. 131258 to 1972 Models

The points are located beneath the cover on the timing case. This is also a 6CA breaker set and the procedure for removal, replacement, and adjustment is exactly the same as described in the preceding section.

Commando 750 (1973) and Commando 850

These models use Lucas 10CA points assemblies driven off the camshaft.

Removal

1. Remove the points cover.
2. To remove the points assembly complete, remove the two large screws which secure the breaker assembly plate. The ignition timing must be set upon installation if the breaker assembly plate is disturbed.
3. To remove individual points, disconnect the wire, being careful of the plastic and fiber insulators at the terminal.
4. Remove the two screws which secure each set of points to the plate (C and D in the illustration).

Installation

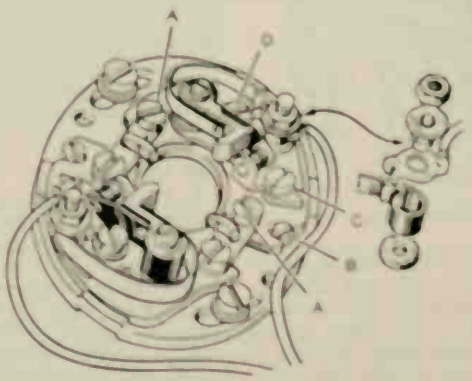
Installation is the reverse of the removal procedure. Assure that the insulating washers and insulator sleeve are correctly positioned. Smear the pivot post with a bit of grease before refitting. Clean new points with a solvent to remove the preservative coating.

Gap Adjustment

1. Turn the engine over until the slash mark on the point cam aligns with the heel of one of the breaker points.
2. Check the point gap. It should be 0.014–0.016 in.
3. If adjustment is necessary, loosen the points securing screws (C and D), and move the point with a small screwdriver until the gap is correct.
4. Tighten the two screws and recheck the gap. Repeat the procedure with the other points set.

Ignition Timing

It is essential that the ignition points be in good condition and correctly gapped before the timing procedure is undertaken.



MAGNETO IGNITION

Adjusting Timing

1. Remove the left and right footpegs and the tachometer drive.
2. Remove the magneto points cover after loosening the kill button wire nut.
3. Place a pan beneath the primary chaincase cover and remove the cover.
4. Take out all of the screws which secure the timing cover. Place a receptacle for oil beneath the timing cover and pull it off, being careful that the conical oil seal fitted to the oil pump nipple is not misplaced.

Oil will dribble out of the drilling in the crankcase. It can be blocked off by inserting one of the cover screws.

5. Remove the spark plugs.
6. Remove the alternator rotor nut and affix the timing disc to the crankshaft.

10CA points assembly

7. The piston must be set to top dead center. Place your thumb over the spark plug hole and kick the engine over slowly with the kickstarter until compression is felt in one of the cylinders. Now place a short thinking screw or a wooden stick into that spark plug hole and turn the engine over using a wrench on the rotor nut until the piston is highest point has been ascertained. Work the piston up and down several times until you are sure that you have it right.

NOTE: There will be about 4° of "loose" movement of the crankshaft which will indicate TDC.

8. Attach a pin wire anywhere that is convenient so that it points to "zero" on the timing disc.

9. Loosen the self-contacting bolt on the timing advance mechanism until the points can be turned freely.

10. Using a small block of wood, or suitable substitute, hold the bob weights of the timing advance mechanism in the "full advance" position.

11. Turn the rotor nut clockwise until the pointer indicates 32° on the timing wheel.

12. Place a very thin piece of paper (cigarette paper is good) between the points and, tapping gently at the paper, ensure that the points are closed, nipping the paper. Retain the points with a wrench on the center nut, maintaining gentle pressure on the paper.

13. The very instant the points begin to separate, the plug will fire. With the small wrench, hold the points at the place that the paper clips out of the points.

14. Turn the self-contacting bolt on the timing advance mechanism with your hand until it is finger tight, then tap the bolt head lightly with a hammer so that the advance mechanism will lock onto the tapered shaft.

CAUTION: A light tap is all that is needed. Do not smash the bolt with any great force.

Tighten the bolt.

15. Turn the engine over once or twice, then recheck the timing.

16. Before reassembling the components, be sure to remove the block from the timing advance mechanism. Check the mechanism for free play.

NOTE: The correct amount of timing advance is 32° of crankshaft rotation which is equivalent to 0.242 in. (6.09 mm) of piston travel. It is possible to use this measurement if the head has been removed, but it would be inaccurate if an attempt is made to measure piston travel through the plug hole due to their angle.

Also, the point of separation for the ignition points cannot be determined with a test light due to the characteristics of the magneto. A special electronic tester, however, can be used if one is available.

CAPACITOR IGNITION

Piston position can be found either with a degree wheel, or with marks on the alternator rotor, depending on model. The moment of point opening can be checked in a number of ways, the easiest being with a test light or a self-powered continuity light.

On later model machines, "dynamic" timing by means of an automotive-type strobe light is possible, and this method is preferable to the "static" methods, since it allows timing to be checked at the rpm at which the engine usually operates.

Early 1967 Models

CHECKING TIMING

1. Remove the left footboard and primary chain cover, placing a pan beneath it to catch the oil.

2. Remove the spark plugs and the ignition points cover.

3. Fit the timing disc onto the crankshaft and place the piston at top dead center. The left cylinder should be on the firing stroke, as indicated by compression in that cylinder as the piston approaches top dead center and clearance at both valves at TDC.

4. The timing, when fully advanced, is 32°. The advance mechanism is behind the points and it is therefore easier to check the timing in the unadvanced position. This is fine on machines which have not covered a large number of miles. In this case, rotate the crankshaft clockwise a few degrees past F as indicated on the timing wheel, then turn it counterclockwise. When the pointer indicates F, the points on the left cylinder should just be beginning to open. Verify this by using a test or continuity light.

For machines with this system which have covered a large number of miles, the timing should be checked in the full advance position since the advance unit does not be worn. To lock the advance unit into full advance position, remove the bolt of the breaker cam and use a screwdriver to turn the cam clockwise until it stops. Using this method, the points should start to open at 32° before top dead center.

ADJUSTING TIMING

To set the timing proceed as outlined above. Loosen the two securing screws which hold the contact breaker plate and move the plate in the needed direction until the points for the left cylinder begin to open at the correct time. The plate is moved clockwise to retard the timing, counterclockwise to advance it.

Be sure to check the timing on the other cylinder as well. If there is a difference greater than 1° between the two, position the breaker plate so as to split the difference.

Late 1967 Models and Commando to Engine No. 131257

CHECKING TIMING

1. Remove the primary chain cover after taking off the left side footplate and the exhaust pipe, if necessary. Catch the oil in a suitable container.

2. Remove the ignition points cover and the spark plugs.

3. Remove the alternator rotor bolt and fit the timing wheel.

4. Place your finger over the right spark plug hole and kick the engine over until compression is felt in the cylinder.

5. Insert a short thinking screw or a wooden stick into the plug hole and continue turning the engine over with a wrench on the rotor bolt until top dead center has been established. Rock the pointer back and forth a few times until you are sure that you have positioned them at the highest point of their travel. Check that the right-hand piston is on the compression stroke by setting clearance at both valves.

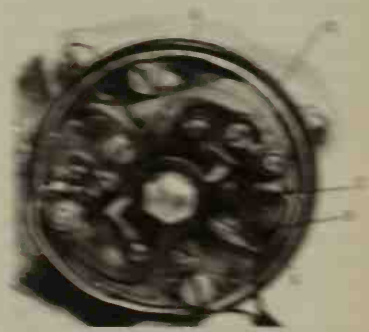
NOTE: There will be about 4° of "loose" movement on the crankshaft which will indicate TDC.

Position for setting timing advance unit

6. Remove the center bolt of the contact breaker cam and find a washer with a hole large enough to fit over the cam shaft and bear on the cam itself. Replace the bolt and the washer, turn the cam clockwise to the full advance position, and tighten the bolt. This should lock the cam in the advanced position.

7. Using a piece of wire as a pointer, position it anywhere that is convenient so that it indicates "zero" on the timing disc.

If you have placed the right cylinder piston at TDC on the compression stroke, you will be working with the points with the black/white primary wire. Hook up the test or continuity light.



8. Rotate the crankshaft backward by turning the rotor nut clockwise several degrees past the normal timing advance as indicated by the degree wheel. This will be either 32° or 29° depending on the model. Turn the crank to about 40° before TDC to ensure that the points are closed.

9. Slowly turn the nut counterclockwise until the timing wheel indicates the correct reading. At this very point the test light bulb should react, for they will commence to open if the timing is correct.

10. Repeat the procedure for the left cylinder.

ADJUSTING TIMING

If the points do not begin to open at the correct time, refer to the illustration of the 4CA points assembly.

4CA points assembly

1. Loosen the two securing screws (A) and turn the brass eccentric screw (B) until the points open at the correct time.

2. If the correct timing cannot be attained in this manner, set the contact breaker at about the middle of its adjustment range using screw (B), then tighten the securing screws.

3. Loosen the large screws which hold the contact breaker plate to the housing and rotate the entire plate until the points begin to open.

4. Secure the two screws. Turn the engine over 360° and adjust the other points set as previously described. It should not be necessary to move the entire breaker plate again, only the individual point set.

Commando Models After Engine No. 131257

These machines have the points assembly mounted in the timing case on the right side of the camshaft and are fitted with a timing mark on the rotor and an indicator plate beneath a cap at the front of the primary chain cover. The system may be checked for proper timing either with the engine running or at a standstill.

CHECKING TIMING

1. Remove the points cover and the inspection plug from the primary chaincase.

2. Hook up a strobe light in accordance with the manufacturer's recommendations.

3. Start the engine and run it at 2,000 rpm so that the timing is fully advanced. The mark on the rotor should register with the 28° mark on the indicator plate. (Each line indicates two degrees.)

4. If no strobe light is available, the engine can be checked at rest. Remove the points cover and the inspection cap on the primary chaincase.

5. Remove the spark plugs. Remove the intake valve rocker cover. Rotate the engine until the drive side (left) intake rocker opens and closes. This will place the drive side cylinder on the firing stroke.

6. Remove the center bolt of the contact breaker cam. With a washer which has a hole large enough to clear the cam post and bear on the cam itself, replace the bolt, turn the breaker cam until it is in the full advance position, and then tighten the bolt.

7. Connect a test light to ground and to the terminal of the LEFT contact breaker (black/yellow primary wire) and rotate the engine until the indicator plate on the primary chaincase reads 28°. The test light bulb should react at this point as the points separate.

8. Repeat the procedure to check the timing for the right cylinder.

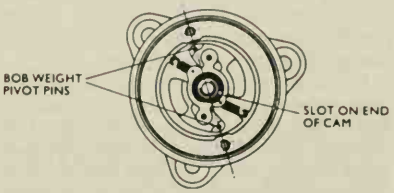
ADJUSTING TIMING

1. Proceed as above. If the points do not open at the correct time, refer to the illustration of the Lucas 6CA or 10CA points.

2. Loosen the securing screws (A) and turn the brass eccentric adjusting screw (B) until the points open at the proper time. Tighten the screws.

3. Rotate the engine 360° and repeat the procedure for the other cylinder.

4. Be sure to remove the breaker cam bolt and the oversized washer, replace the standard washer, and tighten the bolt. Make sure that the advance mechanism works freely.



IGNITION TIMING—WHEN TIMING HAS BEEN LOST

1. If, for any reason, the breaker cam assembly has been removed from its shaft (and this applies to all models equipped with the 6CA or 10CA points system), it is necessary to align it in approximately the correct position before timing can be accomplished.

2. Referring to timing information previously given, locate the drive side (left) cylinder on its compression stroke, and place the piston at 28° before TDC.

3. Place the breaker cam assembly onto its shaft so that the bobweight pivots of the automatic timing advance mechanism line up with the point assembly cover screw holes (see illustration). The slot on the cam face (not the timing slash mark, but the slot) will be at approximately nine o'clock.

4. Set the ignition timing as previously described.

Correct location of timing advance unit

Carburetor Adjustments

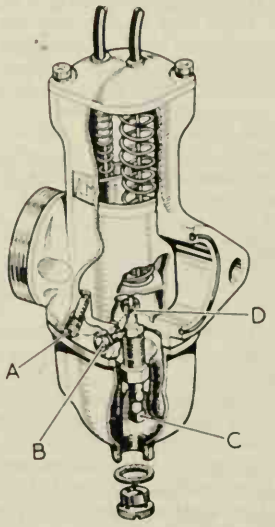
These should be made after the other items in this section have been checked, and when the engine is at its normal operating temperature.

IDLE SPEED AND MIXTURE

1. Turn the pilot air screws in until lightly seated, then back them out about 1½ turns.

2. Turn in the throttle stop screws until idle speed is slightly higher than normal.

3. Remove one of the spark plug leads. Keep the engine running on one cylinder by turning in the throttle stop screw for that cylinder until the engine runs, but as slowly as possible.



4. Turn the pilot air screw in or out until the exhaust pulse from the running cylinder is smooth and even.

5. Connect the spark plug lead, rev the engine a few times to clear it out, then disconnect the lead to the cylinder which has been adjusted.

6. Repeat the previous procedure so that the running cylinder fires as slowly and evenly as possible.

7. Connect the lead. Both cylinders will be running and idle speed will be very high. Back out each throttle stop screw by equal amounts until the desired idle speed is reached.

8. Check that both cylinders are firing evenly.

Concentric carburetor throttle stop screw (A), pilot air screw (B), main jet (C) and needle jet (D)

CARBURETOR SYNCHRONIZATION

1. Remove the air cleaner assembly.

2. Twist the throttle fully open to lift up the slides.

3. Position a mirror behind the carburetors or reach into the carburetor bores with the thumb and index finger of one hand.

4. Slowly close the throttle and watch, or feel, the slides as they are being lowered; they should enter their respective bores simultaneously.

5. If the slide positions are unequal, raise or lower one to match the other by turning the adjuster at the top of the carburetor.

6. Another check is to place a finger on each carburetor slide when the throttle is fully closed, then move the twist grip very slightly. Both slides should begin to lift at the same time. Adjust as described above if necessary.

THROTTLE CABLE ADJUSTMENT

On most models, the cable runs from the twist-grip to a junction block, where two shorter cables run to the carburetor tops. One end of each cable is equipped with an adjuster. These are located at the twist-grip and the carburetor tops.

Adjust the long cable so that there is about 2 mm of free-play before actuation.

Adjust the short cables so that there is as close to zero free-play as possible. Check carburetor synchronization as previously described.

After setting the free-play at each cable, start and warm up the engine. Turn the handlebars from side to side and notice any variation in rpm. If a variation occurs, one of the cables is either incorrectly adjusted (not enough free-play) or is binding somewhere along its routing.

Engine and Transmission

It is important to realize that although the procedures for working on the Norton engine are applicable, with minor variations, to all models, the engine components are usually not interchangeable between Commando and pre-Commando units, even though they may be similar in appearance. Be sure that the correct replacement parts are obtained when necessary.

NOTE: *For engine component inspection procedures, refer to "Engine Rebuilding" under the General Information section.*

ENGINE SERVICE NOTES

1. On all models, the cylinder head and cylinder can be removed without removing the engine from the frame.

2. The clutch and primary drive and timing case components are also accessible for service with the engine in the frame.

3. All transmission components with the exception of the left-side countershaft (or layshaft) bearing can be serviced without removing the transmission.

If necessary, the transmission itself can be removed without disturbing the engine.

4. Most engine work requires only standard tools and a torque wrench. A variety of pullers are needed.

To remove the Commando diaphragm clutch, a special tool *must* be used for safety reasons.

Engine Removal and Installation

COMMANDO

The engine unit may be removed without disturbing the transmission, and this is the easiest method, since removal of the complete assembly requires removal of the rear wheel and swing arm.

1. Remove the seat and fuel tank.

2. Drain the oil from the tank and disconnect the oil pipe junction (one bolt) at the engine. Some oil will come out when the junction is removed.

3. Remove the spark plugs. If necessary, as on late models, unbolt the ignition coil pack and hang it out of the way.

4. Disconnect the tachometer cable at the engine.

NOTE: *On early Commandos with the tach drive box mounted on the outside of the timing case, it is preferable to remove the box itself rather than just the cable, since it is vulnerable to damage if the engine is dropped.*

5. Remove the carburetors complete with manifolds and hang them out of the way by the throttle cable.

6. Remove the exhaust system.

7. Remove the small, engine head steady plates. On models with rubber mounts here, loosen the rubber mount nuts first. Remove the head steady plate from the cylinder head.

8. Remove the gearshift lever.

9. Remove the battery cover. Disconnect the positive terminal of the battery to eliminate the possibility of a short.

10. Disconnect the alternator leads at the snap connectors.

11. Remove the left-side footpeg and the rear brake lever. Remove the primary chaincase cover and remove the alternator, clutch, sprocket, and chain. Refer to "Clutch and Primary Drive."

12. Disconnect the crankcase breather from the engine.

13. Disconnect the ground wire attached to the bottom crankcase stud on the left-side, if fitted.

14. Before removing the mounting plate bolts, provide some means of support for the engine or it will drop several inches before hitting the lower frame rails. A block of wood placed beneath the crankcase is a good idea.

15. Take off the self-locking nut from the bolt which passes through the front engine mount. Withdraw the bolt from the right-side of the frame. Remove the front engine mounting assembly.

16. Remove the rear crankcase mounting nuts and studs, lifting the unit to remove the bottom most stud. Remove the unit from the right-side of the frame.

Installation of the engine and transmission is basically a reversal of the removal procedure.

17. Place the engine in the frame from the right-side of the motorcycle.

18. Fit the three studs and nuts which pass through the rear engine mounting and the crankcase.

19. Supporting the engine, place the front engine mounting assembly in position.

20. Insert the front engine mounting bolt and tighten the self-locking nut to the correct torque setting. Tighten the nuts on the three rear engine mounting studs.

21. Continue reassembly in the reverse of the sequence described for removal.

22. The washers for the finned exhaust pipe nuts should be replaced.

23. Be sure that the exhaust pipe finned nuts are tightened securely. These nuts are best looked after by safety wire fastened by drilling one lobe of the nut and the top cylinder head fin.

24. Check all nuts and bolts for tightness before and after a short ride.

ATLAS

To remove the Atlas engine and transmission as a unit, follow this procedure:

1. Remove the gas tank, disconnecting the fuel lines at the carburetors and taking off the mounting nuts.

2. Remove the head steady bracket.

3. Remove the air cleaner and the carburetors.

4. Drain the oil tank and the engine sump. If work is to be performed on the transmission, drain it also.

5. Unbolt the oil pipe junction at the crankcase. Kicking the engine over a few times after draining the oil tank and before removing the junction will minimize the amount of oil which will dribble out.

6. Remove the exhaust pipes and mufflers.

7. Disconnect the tachometer drive (two screws) at the engine. It is advisable to remove the drive rather than just the cable to avoid hitting it on something as the engine is removed from the frame.

8. Disconnect the battery leads and remove the battery.

9. Remove the rectifier, being very careful of the rectifier bolt.

10. Remove the battery box.

11. Disconnect the crankcase and tank breather hoses to the oil tank and remove the tank (4 bolts).

12. Remove the oil tank platform.

13. Remove the clutch activating lever inspection cap at the top left-hand side of the transmission, pry up the lever with a suitable screwdriver (taking care not to damage the edges of the inspection hole), and remove the clutch cable. Screwing the cable adjuster all the way in makes the job easier. Next, remove the adjuster from the case.

14. Remove both footpegs. Place a pan beneath the primary chaincase cover to

catch the oil when it is removed. Remove the large hexagon nut on the footpeg stud and carefully take off the chrome cover and the rubber washer. Pull off the chaincase cover.

15. Disconnect the alternator leads at the snap connector.

16. Remove the clutch pressure plate by unscrewing the three spring adjustment nuts. These are cylindrical and have two small tabs on the face that bears against the clutch spring to prevent loosening during operation. Removing the nuts will invariably sheer off the tab, making replacement of the nuts advisable. If you must reuse the nuts on the clutch, a knife blade or suitable substitute can be placed between the nut and the spring while removing.

17. Remove the clutch springs and cups.

18. Remove the main clutch nut on the transmission mainshaft and the lock washer. Prevent the hub from turning either with the special tool or by applying the rear brake with the transmission in gear.

19. Remove the three nuts and washers which secure the alternator stator to the stator housing. Pull off the stator.

20. Remove the nut which secures the rotor to the crankshaft and remove the rotor and its woodruff key. A small gear puller is sometimes needed to take the rotor off of the shaft.

21. Disconnect the primary chain. The clutch hub may require a special puller to remove it from the transmission mainshaft, especially if it has not been removed before. In addition, the engine sprocket is fitted onto a tapered portion of the crankshaft and will definitely require a puller. A smaller gear puller can be used in place of the factory sprocket extractor. Be sure to remove the engine sprocket woodruff key.

22. Remove the three screws which fix the stator housing to the mounting plate and the three screws fixing the plate to the crankcase.

23. Remove the nut which is found about halfway between the engine sprocket and the clutch which secures the inner chaincase half.

24. The inner chaincase half is also secured by means of a tab by the nut on the bottom transmission stud. Remove this nut and take away the chaincase half. Disconnect the final drive chain.

25. Proceeding to the four bolts which fasten the upper and lower arms of the engine mounting plates (just before the swing arm), remove the lower bolts and loosen the upper two.

26. Remove the two studs, two bolts, and their respective nuts at the front engine plates.

27. Remove the two bolts which pass through the center stand mounts and the engine mounting plates. Lift the engine and remove the front mounting plates.

28. Remove the engine assembly from the frame.

29. Installation is the reverse of removal.

SCRAMBLERS

For engine service on Scrambler models, note the following points:

1. The engine and transmission are best removed as a unit.

2. The primary chaincase can be left intact during removal.

Refer to removal procedure for Atlas models for initial steps if additional information is needed.

1. Prepare the engine and transmission for removal in the manner outlined for the Atlas, removing the gas tank, exhaust pipes and mufflers, air cleaners, carburetors, oil from tank, and sump.

2. Remove the tachometer drive from the engine, clutch cable at the transmission, oil junction, oil tank and crankcase breather pipes, and alternator connections.

3. Disconnect the rear drive chain.

4. Remove the metal cover over the transmission.

5. Remove the upper front engine mounting bolts. Loosen, but do not remove, the lower front mounts.

6. Remove the right side footpeg and remove the rod from the left side. There are two spacers involved.

7. Unhook the center stand spring.

8. Remove the left side rear engine mounting bolts.

9. Raise the engine slightly to take the pressure off of the lower front bolts which are still in place and remove the nuts. Take away the engine plates, watching for the spacer.

10. Lever the engine forward and lift it up and out of the right side of the frame.

11. Installation is somewhat simplified by first removing the skid plate.

Before replacing the engine in the frame, be certain that the left side footpeg is in its proper position since it cannot be replaced after the engine is in the frame.

12. Begin by placing the engine in the frame from the right side of the bike, rear end first.

13. Insert a length of steel rod or a suitable screwdriver through the rear engine plates and the frame to align the bolt holes.

14. Lever the front of the engine up to replace the lower small mounting bolt and tighten the nuts firmly.

15. Lower the engine and refit the front and rear engine plate bolts.

16. The remainder of the installation procedure is the reverse of the removal procedure.

Top End

REMOVAL

The following procedure gives instructions for removing the head with the engine in the frame.

1. Remove the seat and gas tank. Disconnect the spark plug leads, remove or loosen the plugs; remove the exhaust system.

2. Remove the coil pack, if fitted.

3. On Commando models, remove the head steady side plates, unscrewing the rubber mounting nuts first. Remove the head steady plate from the head.

4. On pre-Commando models, unbolt the head steady from the head and the frame, and remove it.

5. Disconnect the rocker oil feed pipe on each side of the head.

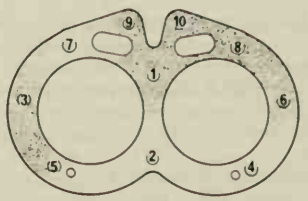
CAUTION: *Each junction has two copper washers. A rag placed over the spark plug hole is a good idea when removing the banjo bolts.*

The rocker oil feed pipe must be placed out of the way so that the head can be removed. On models with neoprene lines, this is not a problem. Earlier machines, however, are equipped with a copper pipe to feed the rockers. This pipe is only flexible to a certain degree. It can be bent out of the way, but take care to avoid crimping it anywhere along its length. The alternate method is to also disconnect the pipe banjo at the crankcase and turn the pipe aside.

6. Remove the exhaust rocker covers and the intake rocker cover.

7. Remove the air cleaner, the carburetors, and the manifolds.

8. On magneto models, removing the front spark plug lead is a good idea.



NOTE: *On Scrambler models, additional steps must be taken at this point.*

a. Remove all of the cylinder head nuts and the bolt on the center of the head. This will leave only the four bolts flanking the spark plug holes;

b. Remove both exhaust rocker spindle retaining plates and remove the spindles. This requires a special tool. Refer to a following section. Be extremely careful of the washer and spring which are found on the spindle;

c. Remove the four remaining cylinder head bolts.

The remainder of the procedure is the same as that for other models.

Cylinder head tightening sequence; reverse the order when removing the head

9. The cylinder head can now be taken off. It is secured to the cylinders by five bolts and nuts. First position the pistons at TDC. Loosen the bolts and nuts gradually and in the reverse of the tightening order shown. There are two long nuts concealed in the fins which require an expecially thin wrench to reach them.

As the last of the fasteners is loosened, the head should begin to rise off its seat slightly, due to the pressure of the valve springs. If the head is not free after the last of the fasteners has been removed, it is probably due to carbon build-up as on engines with many miles on them or those with an oil burning problem. In this event, place a block of wood against the cylinder fins at the exhaust port (the fins are strongest here) and rap sharply with a hammer.

10. The head must be removed very carefully. Remember that there are two

studs at the front of the cylinder barrels and three shorter ones in the head itself which must clear. The most important consideration at this point, however, is the pushrods.

11. Straddle the bike. Lift the head several inches off its seat. Slipping your fingers between the head and barrels, push the four pushrods up into the head as far as they will go. They should only protrude about two inches from the head.

12. Pull the head straight up as far as possible and tilt it backward and to one side until two of the pushrods clear their tunnel. Then tilt it to the opposite side so that the other two are clear. After both sets are out of the tunnels, the head can be taken out to one side.

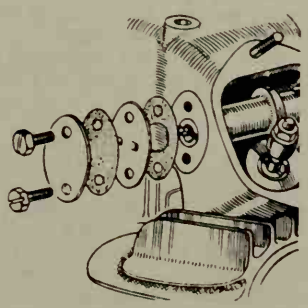
NOTE: *The pushrods are of two lengths. The longer ones activate the intake rockers. These are placed closest to the center of the barrels. Be certain they are correctly located upon reassembly.*

13. The barrels can now be removed. Loosen all nuts securing the barrels to the crankcase. There are nine of them, except on the 850 Commando which has four allen bolts. These should be removed first.

Remove the nuts at the front of the barrels. The others must be loosened as much as possible until they hit the cooling fins. Lift the barrels as much as you can, then loosen the nuts again. Continue until the nuts can be taken off of the studs.

As soon as you have removed the nuts, remove and account for all washers. Be sure that none are left on the barrels, or one can easily fall into the crankcase later.

14. Lift the barrels clear of the crankcase. Ordinarily, the pistons will ride up with them if the transmission is in Neutral. As soon as there is enough room to do so, place a clean rag between the barrels and the crankcase covering the studs. This will catch any pieces of broken piston ring, if there is one, and will lessen the chances of the pistons damaging themselves on the studs as the barrel is pulled off.



CYLINDER HEAD

Maximum allowable warpage across the mating surface is 0.002 in.

ROCKER ARMS

Removal

1. For each rocker arm, remove the rocker spindle retaining plate assembly.

Rocker spindle retaining plate assembly

This consists of an outer plate, a gasket, an inner plate with two tabs to engage the slots of the rocker spindle and assure it maintains its position, and another gasket. Each element in this assembly is different. Note each position carefully.

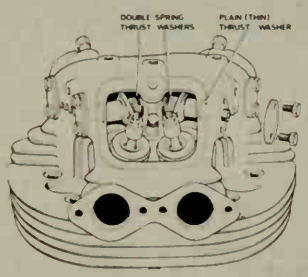
In most cases the parts will remain together when removed, and need not be taken apart.

2. The rocker spindle is press-fit on the cylinder head. First note the position of the slots in the spindle end. Removal is made much easier, and there is less chance of scoring the spindle or the head, if the head is heated first. Ideally, the head should be placed in an oven and heated to not more than 100° C (212° F). In the case of the Scrambler models, where the factory recommends removing the exhaust rocker spindles prior to removing the head (engine in the frame), a propane torch can be used, with caution, to heat the area around the spindle very gently.

The spindles must be removed with a puller. They are threaded internally to accept special tool no. 064298 for late models. Earlier units could accept the pre-Commando cylinder head bolts ($^5/_{16}$ in W). To remove the spindles, a bolt, a locknut, and a short steel sleeve (or pre-Commando clutch spring cup), can be used as a puller. Thread the locknut most of the way up the bolt, then insert it into the sleeve or spring cup. Screw the bolt as far as possible into the spindle. Tightening the locknut will draw the spindle out of the head.

The oil hole in the spindle must face AWAY FROM the center of the head

4. The rocker arm is flanked by a spring washer, fitted on the side closest to the center of the head, and a plain thrust washer on the opposite side. Be positive that both are accounted for. The thickness of the plain thrust washer should be 0.015 in.



NOTE: *The exhaust rockers can be taken directly out of the head after pulling out the spindle. The intake rockers must be turned upside down and then removed on older models.*

6. The ball end is press-fit in the rocker arm. To remove it, support the rocker arm on an appropriate surface to prevent damage to it, then drive the ball shaft out with a drift. The rocker arm has a drilled oil passage from the spindle to the ball end to lubricate the ball and pushrod cup. Make sure that this passage is clear. Also, note that the ball shaft's oil hole must line up with the oil drilling in the rocker. To reassemble, press the ball shaft into position as far as possible. A standard bench vise faced with wood will do the job.

Installation

The rocker arm assembly must be installed correctly or damage to the components will result.

1. The rocker spindle must be located so that the slots on the outer end are HORIZONTAL; the oil hole on the spindle *must* face away from the center of the head.

Rocker arm spindle spring and thrust washer installation

2. Fit the spring washer, the rocker arm, and the thrust washer in their proper locations. Remember that the spring washer is closest to the center of the cylinder head.

3. Heat the head, as was done on removal, and press in the spindle. Make sure that the spindle slots are horizontal to engage with the tabs on the spindle locating plate. Also, check to make certain that the spindle is just below flush with the gasket face on the cylinder head.

4. Fit the spindle locating plate. The correct order, from the head out, is:

a. Paper gasket with large center hole
b. Plate with locating tabs
c. Paper gasket
d. Plain oval plate
e. Two fixing bolts

If oil leaks from the locating plate assembly, it may be due to the spindle protruding even slightly from the head, or the plates themselves may be warped. A late modification has been the fitting of copper washers beneath the plate bolts (Part No. 063129). These may be fitted to all previous models.

VALVES AND VALVE SPRINGS

Removal

1. Take out the stud for the intake rocker cover if you are going to remove the intake valves.

2. Using the valve spring compressor, compress the springs far enough to remove the two tapered valve keepers (collets) and release the spring.

3. The valve collar, inner and outer springs, spring seat, and heat insulating washer can be removed. Keep each assembly separate so that the components

can be reassembled together and in their original location.

4. Remove the oil seals from the guide, if fitted. Remove the valve.

5. Intake valves are larger than the exhaust valves, so telling them apart is no problem. The Commando valves, however, are about 0.07 in. longer than those found on previous models, with a corresponding decrease in the length of the pushrods. The shorter valves can be fitted to the Commando, if necessary, provided that a winkel cap of the proper thickness is installed.

Commando valves cannot be fitted to a pre-Commando engine. The pushrods for Commando and pre-Commando models are in no way interchangeable.

6. Check the valve spring free length, for both inner and outer springs, against the figures given in the technical data. If the measured length is less than 0.187 in. from the standard value, the spring must be replaced. Note that valve springs should be replaced as a set.

Installation

NOTE: *The valve springs are progressively wound, and are installed with the close coils towards the cylinder head.*

1. Put some clean oil on the valve stem and place the valve in the guide.

2. Refit the valve seal, if so equipped. New seals must always be used.

3. Replace the heat insulating washer in its seat, then, the valve spring seat, the springs (close coils against the head), and the spring collar.

4. Compress the spring and slip the two keepers into place.

VALVE GUIDES

Removal

Nortons are equipped with cast iron guides, the newer models being fitted with guides grooved to accept an oil seal on the intake side.

All 750 models have a flange around the guide which rests against the surface of the head when the guide is installed. The 850, however, has a spring clip around the guide which accomplishes the same purpose.

Valve guide to valve stem clearance is 0.002–0.004 in.

1. To remove the guides, strip the head of valves, springs, rocker arms, etc.

2. Heat the head on a hot plate or in an oven. This is essential as the guides are force fit in the head and any attempt to drive them out without heating is sure to result in either a broken guide or a scuffed or enlarged guide bore. Do not heat the head in excess of 200° C.

3. Use a drift to drive out the guides.

If the guides are broken, or have a great amount of carbon build-up as in the case of the exhaust guides, some difficulty will be encountered in removing them. If this is the case, use a chisel to break off the lower portion of the guide which protrudes into the port.

This operation should be an emergency recourse undertaken only after the standard procedure has been attempted.

Installation

1. To replace the guides, again heat the head to 200° C. The guide must be accurately inserted in the bore so that the valve can seat properly. To accomplish this, take the valve, which will be used in the port on which you are working, and place it in its normal seated position. The valve stem will be used to locate the valve guide in the head as it is driven in. Use the drift again, this time from the other end, and press home the guide until the flange or clip, abuts against the head. Guide bore size on all models is 0.3135–0.3145 in. Use the appropriate ream after installation.

NOTE: *The newer Commando 750s have been fitted with oil seals on the intake guides to eliminate the oil burning which was a problem on some motorcycles. The guides are grooved to accept these seals which must* not *be fitted on the exhaust side. These guides are identical in other respects to the previous units, so changing over to a seal-type is possible, if so desired, by simply replacing the old guides with the new units.*

The 850 is also fitted with oil seals on the intake valve guides, although this guide differs from the earlier one (being fitted with a circlip instead of a flange). In both cases, the oil seals go on the intake side only.

Oversized outside diameter guides are available, if needed, in the following sizes over standard: 0.002 in., 0.005 in., 0.010 in., and 0.015 in.

TAPPETS

Removal and Installation

1. The tappets, which are located at the front of the cylinder block, can be checked in place, or removed by cutting the safety wire and taking out the two screws.

The tappets will come out along with the keeper. Note its position for installation.

2. Since tappets are machined in pairs, it is imperative that they be kept together. If either is damaged, they must be replaced in pairs.

3. Grinding or finishing of the stellite pad which contacts the camshaft is not recommended. Replace the tappets if damage occured.

4. When installing, note that the beveled edges of the tappets (running from top to bottom) must face the front of the engine. Use safety wire after tightening the screws.

CYLINDER

1. Measure the bore at the top (½ in. below the lip), middle, and bottom in two directions 90° apart.

2. Rebore the cylinders if the difference between the largest and smallest of the measurements is 0.005 in. (0.13 mm) or greater, or if any of them is 0.008 in. (0.20 mm) greater than the standard bore diameter specification.

3. Pistons for 750s are available in four oversizes in increments of 0.010 in. and 0.010 and 0.020 in. for the 850.

4. When boring, set piston-to-cylinder clearance at 0.0045 in.

PISTONS AND RINGS

Removal

NOTE: *Mark the pistons "L" or "R" and the front or rear to facilitate installation.*

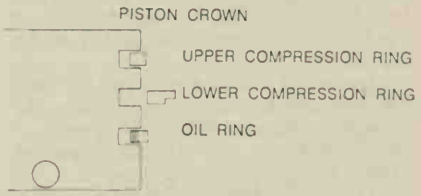
1. Remove the piston pin circlips.

2. Heat the piston crown gently and evenly. Heat only the crown, not the skirt. Push out the piston pin.

Inspection

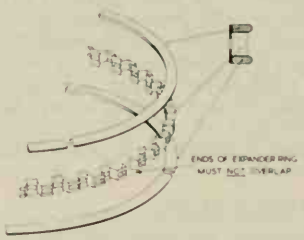
1. Ring side clearance should be 0.0015–0.0035 in.

2. Ring end-gap should be 0.012–0.013 in. Replace the rings if the compression ring gap exceeds 0.014 in.



On multi-piece oil rings, the rails may have an end-gap of 0.010–0.040 in.

Installation

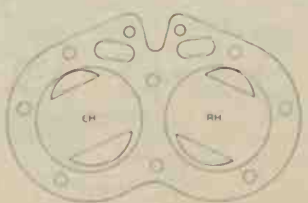


1. The design of the piston rings has been changed several times over the years. The top compression ring is chromed on most models, or red-coated.

NOTE: *Do not remove the red coating if present.*

2. On late models the lower compression ring is tapered, while on others it may be stepped. Be sure the rings are installed with the "Top" mark facing upwards. Stepped rings are installed as illustrated.

Correct installation of stepped compression ring

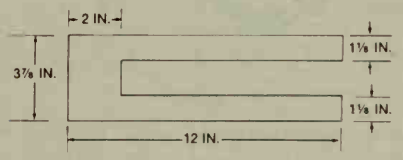


Three-piece oil ring installation

3. Stagger the ring end-gaps around the piston.

4. Fit the pistons to the rods, using new circlips. The rounded ege of the circlip, where applicable, must face the piston.

Be sure the pistons are correctly fitted. 850 models have the crown stamped "RH" or "LH" and the "EX" mark must face the front of the engine.



Piston installation (750)

750 Models have valve cut-outs. The exhaust valve cut-out is closer to the edge of the piston and must be positioned towards the front of the engine.

ASSEMBLY

1. Install the cylinders. Tighten the bolts or nuts in a cross pattern until the correct torque is reached.

Piston stand dimensions

On 750 models, 20 ft lbs for the two small nuts and 25 ft lbs for the others.

On 850 models, 30 ft lbs for allen bolts, 25 ft lbs for the front nut, and 20 ft lbs for the others.

2. Place the pistons at top dead center.

3. Place the four pushrods up into the head as far as they will go, as described in "Removal." The longer pushrods are to be positioned closest to the center of the head.

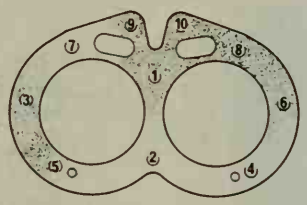
4. Carefully position the head over the barrels, so that the pushrods will drop directly into the tunnels, and take care that the three studs in the head do not damage the gasket.

5. Let the pushrods drop into their tunnels and make sure that they are properly fitted into the tappet cups.

6. Lower the head onto the barrels. The upper end of the pushrods must now fit with their respective rocker arm ball ends.

CAUTION: *On Scrambler models for which the rocker arm had to be removed before taking the head out of the frame, this rocker arm must now be replaced. This is an operation requiring extreme caution lest the washer or spring drop out of reach. It is probably wise to replace the rocker arm now, before bolting down the head.*

7. Support the head about ¼ in. off of the barrels. Those two long cylinder sleeve nuts, which are found beneath the exhaust ports, can be used to support the head in this position.



8. Looking through the exhaust and intake rocker boxes, fit each pushrod with the proper ball end. A short piece of wire with a hook at one end can be used to move the pushrods to accomplish this.

9. When you think you have engaged all of the pushrods, remove the nuts which support the head. Check again. Be absolutely certain all of the pushrods are engaged before proceeding further.

10. Tighten all of the cylinder head bolts and nuts in the order shown. Tightening should be done in increments of 5 ft lbs.

11. Adjust rocker clearances as described in "Tune-Up."

12. The remainder of the assembly procedure is the reverse of that given for disassembly. Before starting, squirt some clean engine oil into the pushrod tunnels, the rocker spindles, and the valve stems.

Cylinder head tightening sequence

13. After the engine has been warmed up, allow it to cool and retorque the head bolts and nuts. After the engine is cold, readjust the valves.

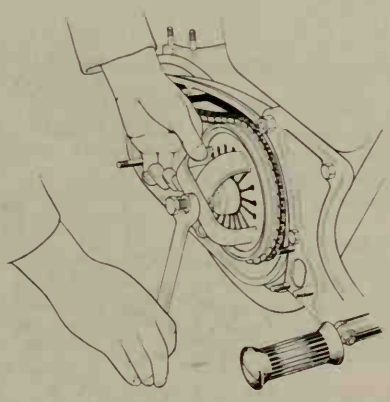
Clutch and Primary Drive

COMMANDO 1974 AND EARLIER

Disassembly

1. Remove the left-side footpeg and place a pan beneath the primary chaincase to catch the oil; take off the chaincase fixing bolt and pull off the cover.

2. Disconnect the alternator wires at the snap connectors. Unbolt the stator and pull the wires (carefully) through the inner chaincase half.

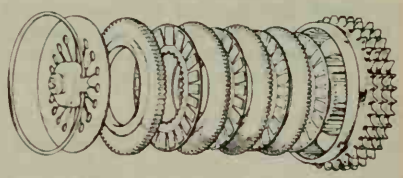


3. Remove the sleeve nut and the lockwasher which secures the alternator rotor to the crankshaft. Remove the rotor, using a gear puller if needed, and take out the woodruff key. Use a pair of pliers if it is tight.

4. The triplex chain is endless variety and, therefore, the engine and clutch sprockets and the chain must be removed simultaneously.

CAUTION: *The clutch can only be removed with the aid of a special tool and it is dangerous to attempt to do so without it.*

5. Loosen the clutch adjuster nut and remove the adjuster screw.



6. With the special clutch compressor tool (Part No. 06-0999), screw the center bolt of the tool into the diaphragm spring center. Tighten the nut on the tool's center bolt until the diaphragm spring is free to turn in the clutch sprocket. Stop at this point.

Using special tool to compress diaphragm spring

7. Remove the large circlip which retains the diaphragm spring (there is a groove provided to make removal easier) and take away the spring and the tool together.

8. Remove the nut and washer which secures the clutch hub to the transmission mainshaft; it is necessary to stop the clutch from turning so that this nut can be broken loose. Use the clutch hub tool (Part No. 06-1015) or a suitable substitute. Alternately, put the transmission in gear and apply the rear brake to remove the clutch nut.

Commando clutch assembly

9. Remove the engine sprocket from its tapered shaft. It is press-fit here and must be removed from the taper with a special tool. The procedure here is to attach the extractor to the sprocket and, after tightening the center bolt, rap it once with a hammer. This should break the sprocket off the shaft. If necessary, a small gear puller can be used instead.

10. The engine sprocket, chain, and clutch hub sprocket can now be taken away. There may be shims behind the clutch hub sprocket. These are used to adjust the true running of the primary chain and should be reassembled in their proper place.

If necessary, a special tool is available which screws into the center of the clutch to aid in removing it from its shaft. It might not be necessary if the clutch has been removed before.

After the assembly has been taken out of the chaincase, remove the engine sprocket woodruff key.

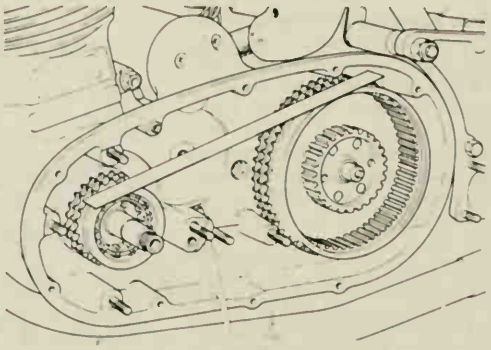
Inspection

1. Maximum allowable plate warpage is 0.012 in. (0.3 mm).

2. Although it operates in the primary chaincase which contains oil to lubricate the chain, this clutch is the "dry" type. The 750's friction plates must have dispersal grooves to get rid of any excess oil which accumulates on them. It may be necessary to cut these grooves if the plate does not have them. Four dispersal grooves spaced 90° apart should be sufficient. On the other side of the friction plate, cut four more grooves offset 45° in relation to the first set and also spaced at 90°.

The plates may have a single groove on each side which is elliptical in reference to the center of the plate.

3. The clutch hub runs on a bearing fitted into the clutch sprocket and located with circlips. To remove the clutch bearing:



a. Take out the small circlip which holds the clutch hub with sleeve extension;

b. Press out the clutch hub;

c. Take out the circlip bearing (the large one);

Commando clutch bearing assembly

Checking alignment of sprocket and clutch

d. Press out the bearing from the inside of the clutch sprocket.

Check the bearing for smooth, effortless rotation. If the bearing is halting or rough, or if there is any play between the outer and inner races, replace it.

Assembly

1. Assembly is the reverse of disassembly.

2. First install the clutch and engine sprockets without the primary chain. Place a straightedge across the sprockets to check that the chain line is true. If adjustment is necessary, add or remove shims behind the clutch sprocket.

3. When installing the assembly, tighten the clutch nut to 70 ft lbs, and the engine (rotor) nut to 80 ft lbs.

4. After installing the alternator stator, check that the gap between the stator and the rotor is even all the way around. The gap should be about 0.010 in. If the rotor and stator touch at any point, or if the gap is obviously not equal at all points, loosen the stator mounts and try to move it to even out the gap. If this is not possible, check for bent mounting studs.

COMMANDO 1975 AND LATER

Disassembly

1. Disconnect the electric starter terminal. Engage First gear. Remove the two bolts from the left footpeg mounting flange.

2. Remove the primary chaincase drain bolt to drain off the oil.

3. Place a large pan beneath the chaincase to catch any residual oil when the cover is removed. Remove the primary chaincase screws and the electric starter locating screw, and remove the cover. Tap the cover with a plastic mallet or the like to free it if stuck.

4. Remove the gearshift cross-shaft.

5. Apply the rear brake and remove the alternator rotor nut and the fan disc washer behind it.

6. Remove the alternator stator after disconnecting the leads, and remove the three stator securing nuts.

7. Remove the alternator rotor. The rotor is keyed to the crankshaft. If it resists, use a small gear puller or pry it off with two screwdrivers. Remove the woodruff key and any shims fitted.

8. Remove the alternator stator mounting plate.

9. Remove the reduction gear assembly, sleeve, and washer.

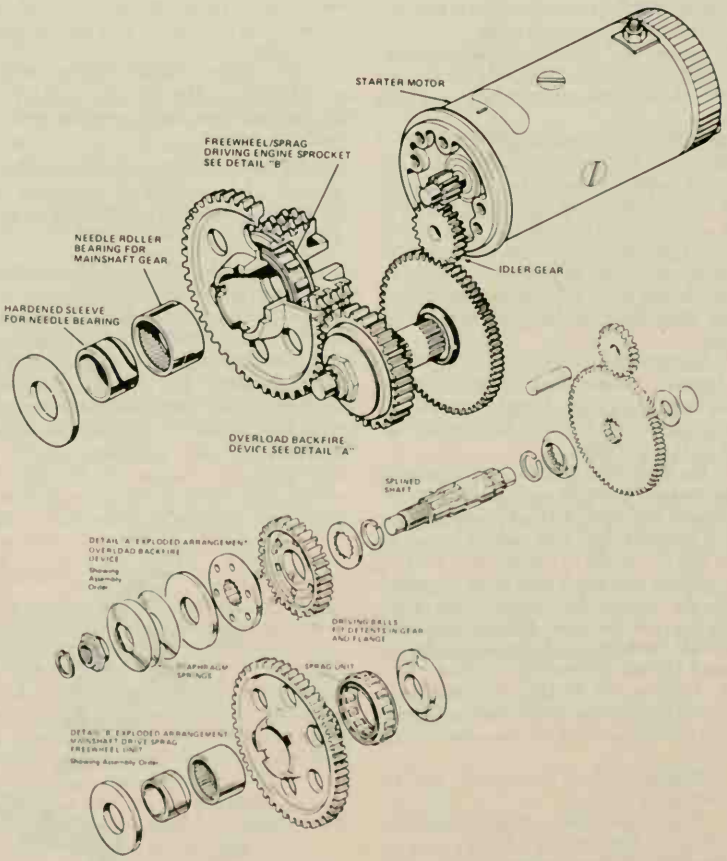
10. Remove the starter intermediate gear shaft with the overload device.

11. Remove the small primary chain tensioner nut, then the two remaining nuts, and remove the tensioner. The tensioner plungers must remain in their original bores so mark them before removal.

12. Loosen the clutch adjuster nut and remove the adjuster.

13. With the special clutch compressor tool (Part No. 06-0999), screw the center bolt of the tool into the diaphragm spring center. Tighten the nut on the tool's center bolt until the diaphragm spring is free to turn in the clutch.

14. Remove the large circlip which retains the spring, and take away the spring and tool together.



15. Remove the nut and washer which secures the clutch hub to the transmission mainshaft. It is necessary to stop the clutch from turning so that this nut can be broken loose. Use the clutch hub tool (Part No. 06-1015). Alternately, apply the rear brake after putting the transmission in gear to remove the clutch nut.

16. Break the engine sprocket off its shaft. The shaft is tapered, and the sprocket must be removed with the special extractor. A small gear puller can also be used.

17. The sprocket, chain, and clutch assembly can now be removed. There may be shims behind the clutch. These are used to adjust the true running of the primary chain and must be reinstalled. If any new components are fitted, the chain line should be checked and shims added or subtracted as necessary.

Inspection

Refer to "Commando 1974 and Earlier" for inspection procedures.

Electric starter drive and reduction assembly

Assembly

1. If the inner chaincase has been removed it must be refitted so that the transmission shaft is perpendicular to the oil seal. Check alignment before bolting up the case.

2. Fit the clutch shaft circlip and the spacer, with the recessed end toward the transmission. Install any spacers which were fitted, and install the engine sprocket and clutch hub and check alignment as outlined under "Commando 1974 and Earlier."

3. After checking chain alignment, fit the large starter gear, then the clutch, sprocket, andprimary chain together. Be sure the engine sprocket is pushed onto its shaft as far as possible.

4. Tighten the clutch nut to 70 ft lbs.

5. Install the clutch plates, first fitting a friction plate, then a steel plate, and alternating until fitting the last (iron) plate. Fit the diaphragm spring with the tool attached, and the large circlip. Remove the clutch tool.

6. Fit the clutch adjuster and locknut.

7. Install the thrust collar into the engine sprocket recess with the small end facing outward.

8. Install the sleeve onto the crankshaft. Fit the starter assembly into the sprocket.

9. Install the large starter gear and bearing over the hardened sleeve and insert it into the assembly.

10. Install the chain tensioner. If the plungers have been removed from their bores, add some oil before refitting. Tighten the nuts gradually, torquing the 5/16 in. nuts to 12 ft lbs, and the 1/4 in. nuts to 5 ft lbs. Use thread locking compound on these nuts. Do *not* overtighten.

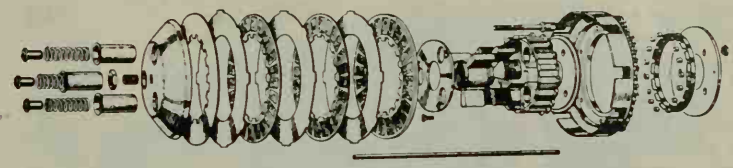
11. Fit the overload device.

12. The remainder of the procedure is the reverse of disassembly. Rotor nut torque is 80 ft lbs. Check that the air gap between the rotor and stator is about 0.010 in. all the way around.

PRE-COMMANDO

Disassembly

1. Remove the left-side footpeg if necessary.



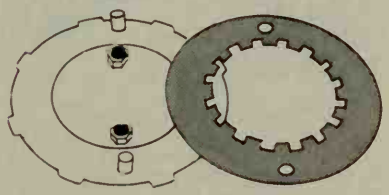
2. Disconnect the alternator leads at the snap-connector.

3. Remove the large hex nut which secures the chaincase cover (or the screws around the cover on Scramblers). Pull off the chaincase, allowing the oil to drip into a suitable pan.

4. On some models, the alternator stator comes off with the chaincase cover. If not, remove it at this time.

5. Remove the rotor nut. Use a small gear puller, if necessary, to remove the rotor. Take the woodruff key out of the crankshaft.

6. Remove the clutch pressure plate by unscrewing the three spring adjustment nuts. Each nut has two small tabs, on the face which bears against the spring, to prevent loosening in operation. It is possible to place a thin knife blade between the spring and the nut to prevent the tabs from being sheared off upon removal. Otherwise, the nuts should be replaced upon reassembly.



Pre-Commando clutch assembly

7. Remove the clutch springs, cups, and pressure plate. Remove the steel and friction plates.

8. Remove the nut and washer which secure the clutch assembly to the transmission mainshaft.

NOTE: *It is necessary to stop the clutch from turning so that this nut can be removed. You can make a simple, though effective, tool to do this. This consists of a standard clutch plain metal plate and a standard friction plate. Bolting the two together takes the place of spring pressure and will make removal of the center nut much easier.*

Tool to stop clutch from turning (pre-Commando)

Alternately, the nut can be removed by engaging the transmission, and applying the rear brake. If the engine is out of the frame, an old length of chain wrapped around the sprocket with one end secured in a vise will serve the same purpose.

9. Disconnect the master link of the primary chain and remove the chain.

10. Using the special tool, if necessary, remove the clutch assembly. This tool screws into the center of the clutch and pulls it off the shaft. It may not be necessary to use the tool if the clutch has been removed before.

11. Using a small gear puller, take the engine sprocket off of the tapered portion of the crankshaft. Remove the woodruff key.

Inspection

1. Maximum allowable plate warpage is 0.012 in. (0.3 mm).

2. Friction plates which have become oil-impregnated through long service should be replaced, although it may be possible to salvage them for awhile by dusting with an oil-absorbing compound, and washing in a mild solvent.

3. The clutch hub studs, if damaged or bent, can be removed by removing the nuts on the back of the clutch hub. The nuts are peened for security, and should be replaced rather than reused. Be sure to peen the nuts after tightening them securely.

4. The clutch has rubber shock absorbers in the hub to prevent "snatching" and the damage it might cause. To inspect them, remove the three countersunk retaining screws from the front of the clutch hub and pry off the steel plate. The rubber blocks will come out of the hub easily if they are worn.

Assembly

Assembly is basically the reverse of the disassembly procedure. Note the following points:

1. Be sure to install the chain masterlink spring clip so that the closed end faces the direction of chain rotation.

2. When assembling the clutch, first fit the housing and hub. Install the engine sprocket onto the crankshaft with the boss outward. Fit the primary chain.

3. Install the clutch plates, noting that the single-sided friction plate is installed last with the steel side outward.

4. Replace the spring cups and springs; the cups have a tab to fit a slot on the pressure plate.

5. Screw down the adjusting nut with a fork-like tool. These should be flush with the spring cups after assembly.

6. Replace the rotor and tighten the rotor nut very firmly. It is advisable to secure this nut with thread locking compound.

7. Bolt on the alternator, run the leads through the inner chaincase half, and reconnect them.

8. Kick the engine over several times while watching the rotor, to be sure that it does not contact the alternator stator at any point. An even gap all around the rotor is preferred and washers may be placed behind the stator to accomplish this.

A spacer, about 0.010 in. thick, can be placed around the rotor and used as a guide while tightening the stator nuts.

9. Work the handlebar clutch lever several times and notice the operation of the clutch. The pressure plate must remain parallel to the other plates when it disengages. If it does not (you will notice it coming off the assembly at an angle), adjust the clutch springs.

10. Adjust the clutch as outlined in "Maintenance."

Timing Case

All of the valve and ignition timing gear on the Norton 750 and 850 is contained in the case on the right-side of the crankcase. The oil pump as well as several important oil seals and junctions for the lubrication system are found here also.

The timing is accomplished by means of a small pinion which is fitted to the end of the crankshaft and drives an inter-

mediate gear and sprocket. This sprocket drives the camshaft by means of a short, single-row chain. The oil pump drive gear is also located on the crankshaft.

Commando engines after No. 131257 have the ignition points operating at the right end of the camshaft. Prior to this model, Commandos had the points located in a canister behind the cylinder barrels. The points were timed by another chain from the intermediate sprocket to the distributor sprocket which was secured to its shaft by a pin.

Most other Nortons, including the Atlas and G15CS, were equipped with the Lucas K2F magneto. This unit, too, was located behind the barrels and it was also driven by chain from the intermediate sprocket. The automatic spark advance mechanism for the magneto was integrated with the magneto sprocket and they were secured to the magneto's tapered shaft with a self-locking bolt.

TIMING COVER

Removal

To remove the timing cover, follow the procedure outlined below, with attention to variations for particular models.

1. Disconnect the tachometer drive if it is mounted on the outside of the timing cover.

2. Remove the ignition points cover (after engine No. 131257).

3. Remove the rocker oil feed pipe banjo at the rear of the timing cover. If the engine has been recently run, a little oil may dribble out.

AFTER ENGINE NO. 131257:

4. Remove the ignition point base plate which is secured by two screws, also the wires. It may be helpful to mark the location of the base plate before removal, so that it can be reinstalled without the necessity of resetting the timing.

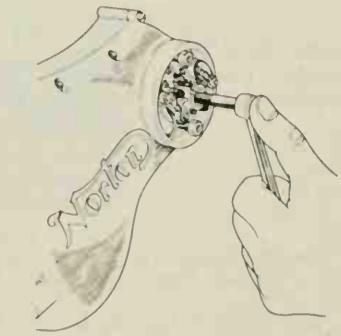
5. Remove the automatic timing advance center bolt.

6. Screw a withdrawal bolt (Part No. 06-0934) into the center of the advance mechanism to pull it off of the camshaft. Slide hammer 06-4298 can also be used.

ALL MODELS:

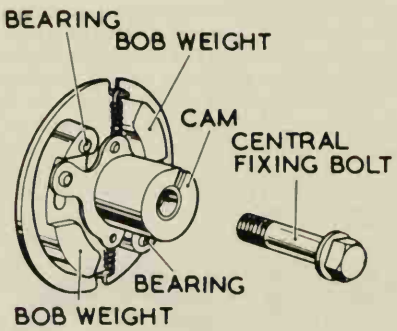
7. Place a can beneath the cover to catch the oil. Take out the timing cover screws. There are twelve of them and they are of three different lengths, so note their positions.

8. Pull off the timing cover. If difficulty is encountered, tap around the cover very lightly with a rubber mallet until the cover can be separated. Often a commercial brand of penetrating fluid can be used to break the seal.



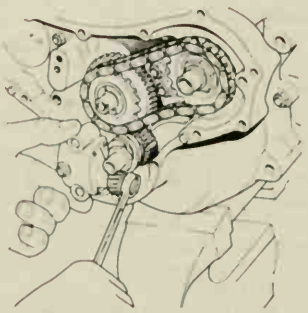
Note the oil seal plunger and spring fitted to late 850 models.

9. Oil will dribble out of the drilling in the crankcase at the left (as you look at it) of the timing case. Use one of the cover screws to block off the flow of oil.



TIMING ASSEMBLY

Removal



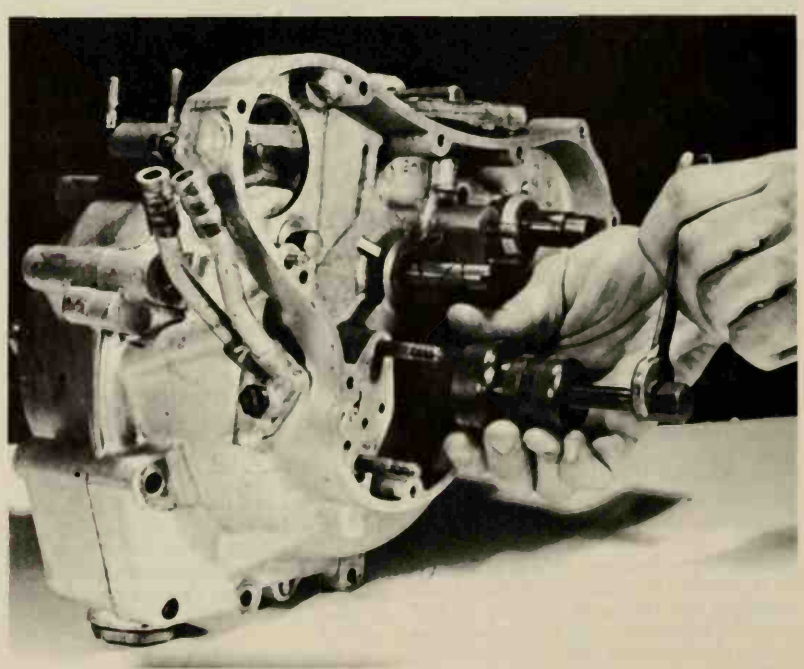
If the sprockets and chain are to be removed, mark both with paint before removal.

Removing the advance mechanism

Timing advance mechanism

Removing the oil pump

Removing the camshaft sprocket nut



1. Remove the oil pump. It is secured by two nuts. Make sure that the pump has the conical oil seal fitted on the nipple of the pump body. Sometimes this seal comes away with the timing cover, so check there if it is missing. Note the presence of any shims behind the seal.

2. Remove the oil pump drive gear. This has a LEFT-HAND thread onto the crankshaft.

3. Remove the camshaft chain adjuster. This assembly consists of two plain metal plates of varying thickness and a metal slipper which bears on the cam chain and it is fastened by two nuts. The thin metal plate goes on the engine side of the slipper.

4. Remove the nut which secures the camshaft sprocket. The sprocket can be taken off with a gear puller or with the extractor tool (Part No. EST12). The cam sprocket cannot be removed at this point on models with a separate ignition timing chain. For these models:

5. Loosen the magneto sprocket bolt and make sure that the automatic advance mechanism can be removed from

Removing the timing pinion

the magneto shaft or, on capacitor ignition models, drive out the pin passing through the distributor sprocket and shaft.

6. Remove the intermediate sprocket, cam sprocket, and ignition sprocket (if applicable) together. Pinch the chain or chains in the center of their runs to ensure that the sprockets do not change their position on the chain relative to the intermediate sprocket. Remove the thrust washer behind the intermediate sprocket if fitted. Take the woodruff key off of the camshaft.

7. Remove the small timing pinion from the crankshaft. This necessitates the use of the special extractor (Part No. ET2003).

Remove the pinion key, the triangular washer, and the metal oil seal from the crankshaft.

Inspection

1. Check for cracks in the cam chain adjuster slipper. This can occur if the chain had been overtight. Allow for proper play upon reassembly.

2. The magneto or points canister have a small amount of movement on their mountings to adjust the chain tension. Once this movement has been used up, the chain must be replaced.

Installation

1. Replace the metal oil seal, the triangular washer, and the pinion key on the crankshaft.

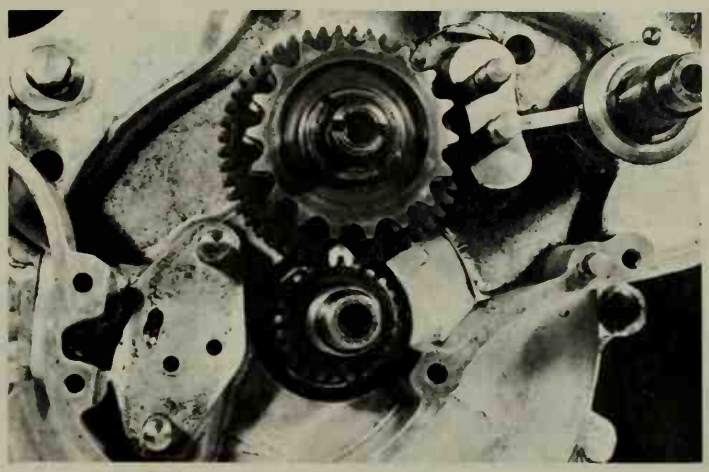
2. Replace the pinion. Be sure the bevelled edge faces outward. there is a timing "dot" on the outer side of the pinion also.

3. Replace the thrust washer on the intermediate shaft if fitted.

4. Rotate the crankshaft until the small timing dot on the timing pinion is at 12 o'clock.

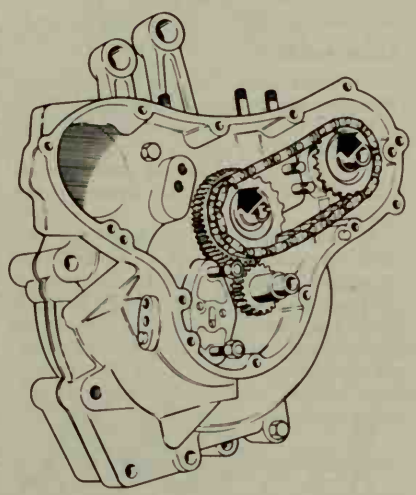
5. Take the cam timing chain with the intermediate sprocket and cam sprocket, and the ignition timing chain and sprocket if applicable, and position the intermediate gear so that its timing dot aligns with that on the timing pinion.

6. Also fit the cam sprocket on the cam. It is keyed.



7. If the timing has been preserved—fine, but if you are not entirely sure, there is an easy check. There are timing dots on both the intermediate sprocket and the cam sprocket. When the intermediate sprocket is in the correct position, there should be SIX outer plates of the drive chain between the two dots.

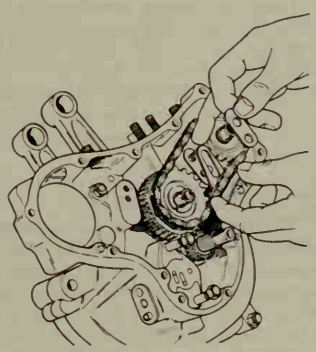
8. Replace the distributor or magneto sprocket. If a magneto is fitted, do not tighten the fixing bolt all the way, as the timing must be reset.



9. Stop the engine from turning by placing the transmission in gear or, if the engine is disassembled, place a steel bar through the connecting rod small ends and the bearing on the top of the crankcase. Tighten the camshaft sprocket nut.

10. Replace the oil pump drive gear on the crankshaft (left-hand thread) and tighten it also. The nut should be very tight. Some thread locking compound here is a good idea.

11. Apply a thin coat of gasket compound on the face of the oil pump unless a gasket is fitted, and replace the pump on its studs. Tighten the two nuts evenly and torque both to 15 ft lbs.



Timing pinion and intermediate sprocket marks aligned

Cam chain correctly timed (six chain plates between the dots on the sprockets)

12. Replace the thin metal plate on the cam chain tensioner with the longest portion from the bolt hole downward.

13. Replace the tensioner slipper itself and, finally, the thick plate. Replace, but do not tighten, the two nuts on the tensioner.

Installing the cam chain tensioner

14. The cam chain tension must now be adjusted. A cut-away timing cover is handy to have for the adjustment of the chain, since it supports the intermediate sprocket spindle and allows a more accurate setting of the chain slack to be made.

1975 and later models have an inspection hole in the timing cover for this purpose.

The tensioner should be adjusted to bear against the lower chain run until there is 3/16 in. play measured in the middle of the upper chain run.

15. If an ignition chain is fitted, this can be adjusted (also to 3/16 in. play in the middle of the upper run) by loosening the two nuts and one bolt which secure the distributor or magneto, and pivoting the unit until the desired tension is reached. A screwdriver can be used to pry behind the unit, as there is a shoulder provided on the case for this.

CAUTION: *Overtightening of the magneto chain can cause binding of the automatic spark advance mechanism. Therefore, ensure that the chain slack is correct and that the advance mechanism moves freely after the timing is adjusted.*

TIMING COVER OIL SEALS

1. To remove the large seal, take out the circlip which secures it and pry the seal out.

2. When replacing the seal, gently heat the cover with a propane torch or suitable replacement and fit the seal with the metal face outward (toward you as you install it).

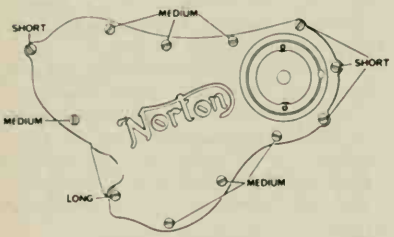
3. The smaller seal is present on machines after engine No. 131257 and is intended to prevent oil from getting into the points compartment. It fits directly over the camshaft. Pry out the seal with a sharp pointed tool.

4. Warm the cover as before and press the seal into position, metal backing facing you as you install it.

5. The timing cover also has the oil pressure relief valve which is located just above the rocker oil feed pipe junction. The relief valve is spring-loaded to operate at a predetermined pressure and, therefore, needs no attention. The valve does have a wire filter screen fitted which

might be checked and cleaned if necessary.

TIMING COVER



Installation

1. Remove all traces of old gasket and gasket compound from the mating surfaces. The timing cover can be worked on an appropriate surface (such as a sheet of emery cloth placed on a piece of glass) to remove any surface irregularities, scratches, etc.

NOTE: *Early model Nortons had a rather thin paper gasket for the timing cover which was effective only if the mating surfaces were in very good condition. The Commando has a thicker gasket which may be used to advantage on earlier models also. The only difference between this and the earlier gasket (aside from the thickeness and composition of the material) is an extra hole for the points wires. This is not needed for early models and can be removed.*

2. Models fitted with the ignition points at the camshaft must use a guide bush (Part No. 06-1359) over the cam to prevent damage to the oil seal in the timing cover. The threaded portion of the bush is screwed on to the camshaft by hand, as far as possible. Add a little oil to the outside of the bush to make assembly easier.

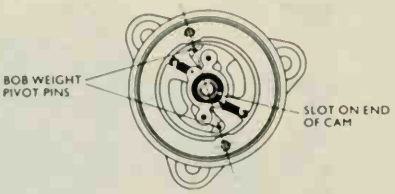
3. Check the condition and efficiency of the conical seal on the oil pump. If it is deformed, replace it. It should be able to push the timing cover away from the case about 0.010 in. when fitted. If it does not, replace it, or use shim washers behind the seal.

Timing cover screw locations

If the thicker gasket has been fitted to early models, shim washers may be necessary.

4. Refit the timing cover, screw in the 12 cover screws, and tighten them evenly and in a diagonal pattern.

5. Reconnect the rocker oil feedpipe banjo.



6. Reconnect the tachometer drive cable if applicable.

For Commando models after engine No. 131257:

7. Remove the inspection cap on the primary chaincase to expose the indicator plate.

8. Position the engine so that the timing mark on the rotor registers 28° on the indicator plate (each mark equals two degrees).

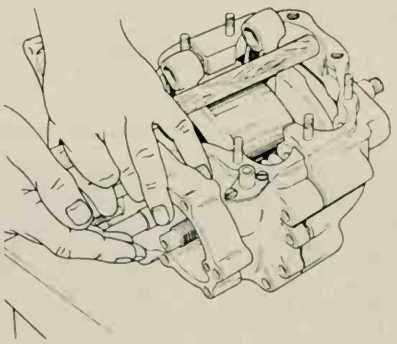
9. Insert the timing advance mechanism and position it so that the rivets for the bob weights are in line with the two

Timing advance mechanism positioned for installation

screw holes for the point cover. The slot (not the slash mark) in the breaker cam should now be about 9 o'cock.

10. Replace the ignition point base assembly. The yellow and black lead is for the drive side cylinder (left point set).

11. Adjust the timing.



Bottom End

Disassembly

1. Remove the engine from the frame. Remove the primary drive and clutch, cylinder head and cylinders, timing cover and timing gear, etc.

2. Unbolt the crankcase studs and remove the screw(s) at the bottom of the cases.

3. Tap against the inside of the left-side crankcase half with a plastic mallet or wooden block to separate the cases. If difficulty is encountered, gently heat the drive side bearing boss. This should only be necessary on relatively new engines.

Separating the crankcase halves

4. Take out the camshaft, and the crankcase breather plate and spring, if fitted.

5. Heat the timing side bearing boss, holding the right-side crankcase half, and tap on the timing end of the crankshaft with a plastic mallet to free it.

NOTE: *It is a good idea to use a sleeve over the crankshaft end to avoid damage to it or to the oil pump worm gear threads.*

6. Bearings can be removed from the crank by prying them off.

7. To remove bearing races from the crankcases, heat the case in an oven (not to exceed 200° C), then drop the case onto a wooden block from about a 6 in. height. If removal is difficult, the bearing race can be cooled, after the case is heated, either with a damp rag, or by running an ice cube around the race.

8. The drive side oil seal can be punched out after removing the bearing race. Late models are equipped with a circlip which must be removed before the oil seal.

Assembly

1. Assembly is the reverse of disassembly.

2. On models with a cam-timed crankcase breather, refusal of the case halves to mate is sometimes due to the engaging dogs on the breather plate not properly engaging the camshaft.

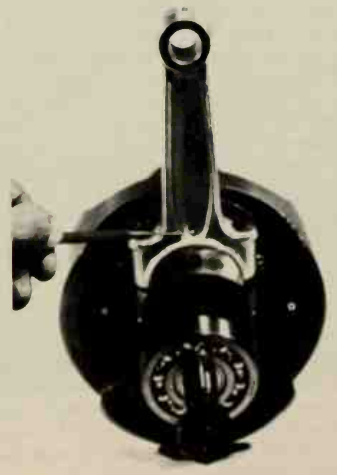
3. On models with a roller bearing on the timing side, insure proper lubrication by pouring clean engine oil into the intake rocker box after engine assembly is completed. This oil will drain into the timing case, and then to the bearings.

4. Be sure that all bearings and bushings are well lubricated before reassembling the rest of the engine.

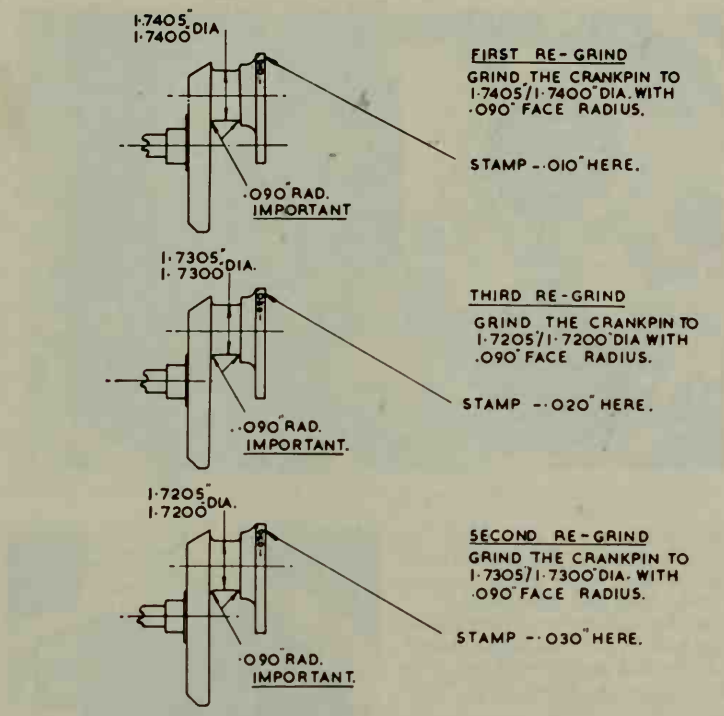
CONNECTING RODS AND JOURNALS

Removal and Installation

1. To remove the rods, remove the rod bolt nuts and pull the rod off the journal with a sharp jerk.



2. Be sure to keep each rod with its own cap. Rods and caps are machined together, and it is essential that the rod-and-cap assemblies be kept separate. In addition, note that there is a slash mark on each which indicates the correct cap position.



Connecting rod assembly

3. Rod journals must be within 0.001 in. of perfectly round. Minor scoring can be removed with fine emery tape, but if the journal is oval, or heavily scored, it must be reground.

If the crankshaft is reground, be sure that a 0.090 in. radius is restored on the journal shoulder.

The oil hole at the base of the rods must face outwards

Crank regrinding dimensions

4. Undersized big end bearings are available in four sizes: 0.010 in., 0.020 in., 0.030 in., and 0.040 in.

The size of the replacement bearing should be stamped on the end cheek.

5. There is no bush at the rod small end, the piston pin riding directly on the rod itself. Small end diameter should not exceed 0.6868 in.

6. Assembly is the reverse of removal. Be sure that the mark on each cap aligns with that of its own connecting rod. Install the rods with the oil hole at the lower end pointing AWAY FROM the center of the crankshaft.

7. New rod bolt nuts must be used, and the use of new bolts is recommended as well. Tighten thse nuts to 25 ft lbs.

8. Be sure the big end bearings are well lubricated before assembly.

CRANKSHAFT

Disassembly and Assembly

The crankshaft is a three-piece unit consisting of a center flywheel and two end cheeks which incorporate the rod journals. The crank is bolted together.

1. Mark the positions of the cheeks and the flywheel to eliminate the chance of accidental interchange.

2. Straighten thelock tabs, if applicable, then remove the crankshaft nuts and separate the pieces.

3. Clean out the sludge trap machined into the flywheel.

4. Before assembly, be certain that the mating surfaces are absolutely free of foreign matter.

5. Nuts are torqued to 35 ft lbs on 750s and 30 ft lbs on 850s. Tighten in a cross pattern. Turn up the locking tabs, if fitted. If not, peen the nuts with a punch to lock them in position.

CAMSHAFT

1. After splitting the cases, make the usual inspections of the cam and cam bushes. The bushes must be free of wear or score marks. If replacement is necessary, heat the cases and drive the bushes out. When installing new bushes, align the oil hole in the bush with that in the crankcase.

New bushes must be reamed to size after installation.

Important: Either the cam bushes or the cam itself must be fitted with oil distribution grooves or damage will result. If the camshaft does not have oil grooves, obtain and install grooved bushes.

Transmission

The transmission is basically the same on all models covered here, the major change being the introduction of the left-hand shift for 1975 and later models.

GEARBOX REMOVAL AND INSTALLATION

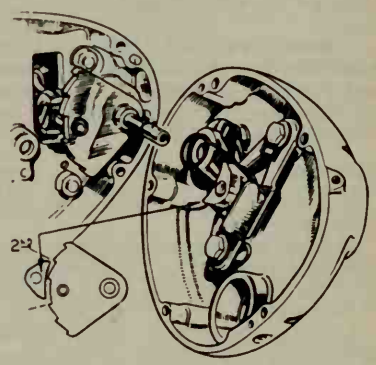
1. Removal and replacement of all gearbox internal parts with the exception of the layshaft left-side bearing is possible without removing the gearbox shell from the frame. If removal of the entire unit is desired, the engine must be removed on 1969 and earlier models.

2. On 1970 and later units, remove the clutch and primary drive assembly. Remove the rear wheel. Disconnect the chain.

3. Remove the three rear crankcase-to-engine plate bolts or studs.

4. Support the motorcycle on a large block of wood or a crate, remove the rear wheel and the center stand.

5. Remove the top and bottom mounting bolt and stud. Turn the gearbox counterclockwise as far as possible. Push the rear engine mounting towards the rear of the motorcycle, until the cutaway at the bottom right is clear of the crankcase, and continue rotating the gearbox until it can be removed.



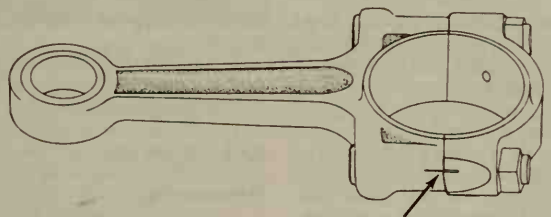
In some cases it may be necessary to remove the front main mounting bolt for extra clearance.

6. Installation is the reverse of the above.

OUTER COVER

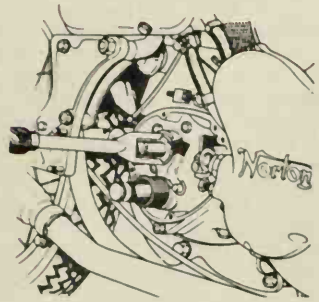
Disassembly

1. Take off the clutch lever inspection cap on the outer cover and disconnect the clutch cable by prying up the lever and slipping out the nipple. Unscrew the cable adjuster from the case. Drain the transmission oil.



Gearbox outer cover assembly

2. Remove the kick-starter crank bolt and remove the crank. It might be necessary to use a claw-type puller to get the crank off the splined shaft.



3. Remove the right footpeg.

4. Remove the bolt for the gearshift lever, but leave the lever in place.

5. Remove the five screws which secure the outer cover.

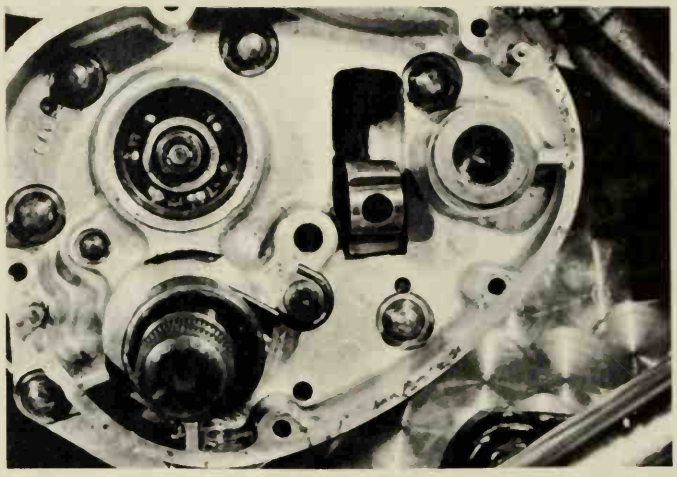
Caps must be installed so that the slash mark on rod and cap align

Removing the clutch operating lever

6. Carefully pull off the cover, using the gearshift lever to assist you.
7. Remove the pawl spring.
8. Disengage the shifter return spring legs from the pawl pin, and withdraw the pawl carrier, tapping it if necessary.
9. Remove the shifter stop plate (two bolts), and remove the return spring.

Inspection

1. Check the shifter pawl for unusual wear.
2. The outer cover has two rubber O-rings which act as oil seals. The larger of the two is found on the kick-starter shaft behind a steel bush. The bush may be removed by heating the case and driving it out from the outside after first prying out the O-ring.
3. The smaller O-ring is for the gear shifter shaft. To remove the bush here, heat the cover, gently screw a coarse threaded tap into the bush, and pull it out.
4. Remove any traces of old gasket material from the outer cover mating surface and check the condition of the surface. All abrasions, scratches, etc. should be removed with an oil stone.



Assembly

1. Assembly is the reverse of the previous procedure.
2. When refitting the pawl spring, notice that the cranked leg of the spring will be in the lowest position, the straight leg in the higher.
3. Assure that the pawl concave side is facing the gearshift spindle so that it can remesh with the ratchet plate.
4. Put some clean oil on the kick-starter shaft to avoid bruising the O-ring on reassembly.

INNER COVER

Disassembly

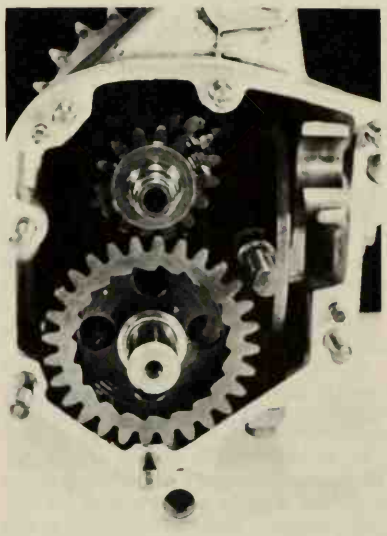
1. Remove the ratchet plate with spindle.
2. Unbolt the clutch operating lever and remove it and its roller from the shaft.
3. Mark the position of the slot in the clutch operating lever shaft on the inner cover so that the shaft can be reassembled in the correct position to give the clutch cable a straight pull. On recent models, the assembly is already marked.
4. Unscrew the lockring on the clutch lever shaft and remove the lockring, the shaft, and the ball.
5. Remove the mainshaft nut which will be exposed after removing the shaft.

Inner cover ready for removal

6. Remove the seven nuts which secure the inner cover to the gearbox shell and pull off the inner cover, tapping lightly at the front end if necessary.
7. Take the kick-starter return spring out of the hole in the kick-starter shaft.
8. Pull the kick-starter shaft out of its bush from the inside of the cover.

Inspection

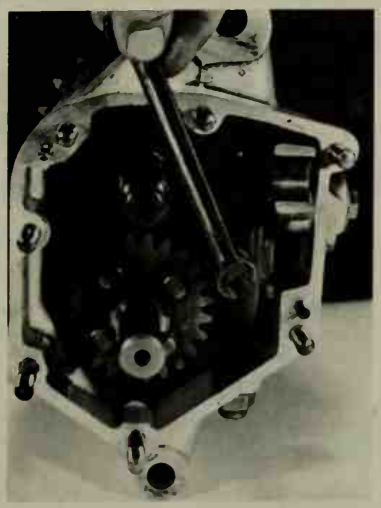
1. Check the mating surfaces of the inner cover for scratches, abrasions, or knicks. If present, these may be removed with emery cloth. In addition, place the cover on a flat surface, such as a piece of glass, and make sure that it is flat.
2. Check the mainshaft bearing for excessive play, roughness or binding in rotation, or obvious marks of wear. Replace the bearing if necessary by heating the case gently and driving out the bearing.
3. If the kick-starter bush is worn, it can also be removed after heating the case. After the new bush is driven in, it should be reamed to 0.6875–0.6865 in.
4. Check the condition of the kick-starter pawl very carefully. Be sure that the pawl shows no signs of wear or chipping along the edge. The pawl is easily replaced by removing the pin. If this is done, watch for the plunger or spring.
5. Examine the kick-starter stop-piece and the pawl cam which are riveted to the inner cover. Check for looseness on the rivets and re-rivet the stop-piece if necessary.



Assembly

1. Assemble the inner cover in the reverse of the disassembly procedure. Be certain that the clutch operating lever shaft is correctly aligned to give the cable a straight pull.
2. Be sure that the mating surfaces are clean and in good condition. Refit a new gasket.
3. Tighten the inner cover nuts evenly and in a cross pattern to 12 ft lbs. Fit and tighten the mainshaft nut.

GEAR CLUSTER



Disassembly

1. Proceed with the disassembly procedures outlined above. Removing the inner cover will expose the gear assemblies on the two shafts. The upper shaft is the mainshaft and the lower is the countershaft (or layshaft).

Gear cluster and shifter assembled

2. Remove the low gear pinion on the mainshaft. Note that the boss on this gear faces outward.
3. Unscrew the shifter fork spindle and remove it.
4. Remove the shifter forks.
5. Remove the clutch pushrod from the mainshaft.
6. If the clutch has been removed, remove the mainshaft and the gears on it. The sleeve gear will remain in place.
7. Take out the layshaft and the layshaft gears.
8. If disassembly is required past this point, it is necessary to remove the primary chaincase, etc., to gain access to the transmission sprocket.
9. Remove the screw which secures the lock plate on the transmission sprocket.
10. Remove the transmission sprocket nut, which has a LEFT-HAND thread, and remove the sprocket from the shaft.
11. Remove the sleeve gear from the bearing.

Removing the shift fork spindle

12. Remove the dome nut at the bottom of the transmission case and take out the plunger and spring. Remove the neutral switch, if fitted.

13. Remove the bolt fixing the quadrant and the bolt which secures the camplate and remove these components.

14. To remove the layshaft bearing, it is necessary to remove the case. Heat it in an oven (do not exceed 200° C), then tap the case with a plastic mallet to knock out the bearing.

15. The mainshaft bearing can be removed after prying out the oil seal and again heating the case, driving out the bearing with a suitable drift.

Inspection

1. Check the condition of the mainshaft and layshaft bearings. All bearings should rotate with little friction and should be smooth throughout.

2. The bushes for the camplate and quadrant mounting bolts should be checked. Wear would make shifting difficult. The bushes may be removed by heating the case and tapping them out.

3. There are O-ring oil seals on both the camplate and the quadrant. If oil leakage is noticed at the bolts for these components, the seals should be replaced.

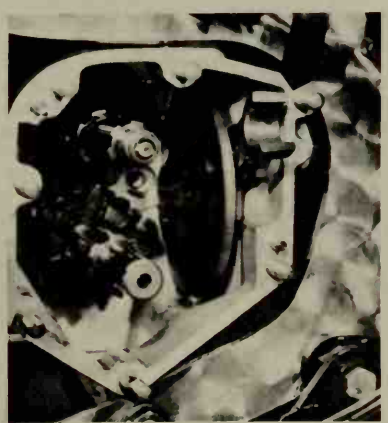
4. Examine the gear bushes. They should be free from any score marks and have a smooth finish.

Except for the layshaft first gear and the sleeve gear, the bushes are a slip fit in the gears. Replacement bushes are easily fitted.

Layshaft first gear and sleeve gear bushes are pressed in; on late models the sleeve gear bushes are secured by snap-rings. These bushes must be checked in place since removal will destroy them. New bushes are pressed into the gear after chilling the bushes in a freezer for several hours (heating the gear will not work), and must be reamed to the proper size after installation. Do not attempt to replace the bushes unless the correct size reamer is available.

Assembly

1. Fit the mainshaft and layshaft bearings in the case by driving them in. The case should be heated slightly to aid installation. Note that the mainshaft bearing is installed with the sealed side outward. Do not forget the spacer which fits in the mainshaft oil seal.



2. Fit the shifter quadrant, securing it with its bolt and washer. Raise the quadrant so that the very top arm is in line with the top right-hand stud on the transmission case.

3. Insert the cam plate, positioning it so that only the first two teeth on the quadrant are visible through the camplate slot. When the camplate plunger is fitted, the plunger will rest in the High gear notch of the camplate. Secure the camplate with its bolt and washer. Fit the camplate plunger, spring, and domed nut.

4. Replace the sleeve gear, making sure that the spacer which bears on the oil seal is in position.

5. Fit the transmission sprocket and secure it with its nut. The nut has a left-hand thread. Tighten it firmly. Hold the sleeve gear in position to tighten the nut by wrapping a length of drive chain around the sprocket and securing one end. Fit the locking plate and screw.

6. Fit the third gear onto the layshaft noting that the boss on this gear faces the fourth layshaft gear. Tap the fourth layshaft gear onto its shaft. Note that this gear has a small boss on one side which must face the layshaft bearing.

7. Install the mainshaft with the third gear in place on the shaft. Install the layshaft with third and fourth gears in place.

NOTE: *The layshaft should be pressed into its bearing by hand and should be reasonably tight once in place. If the shaft cannot be inserted by hand, use a fine emery cloth to work the end of the shaft until this is possible. Otherwise removal of the shaft will be very difficult.*

8. Install the mainshaft second gear complete with its shift fork, engaging the shift fork stud into the camplate slot. Note that the camplate may be rotated to the Neutral position (shallow notch), to facilitate installation.

9. Install the layshaft second gear complete with its shift fork and engage the fork stud into the camplate stud. Line up the bores of the shift forks and install and tighten the shift fork spindle.

10. Fit the first gears, noting that the boss on the mainshaft first gear faces outward.

11. Install the roller into the shifter quadrant holding it in place with some grease if necessary.

NOTE: *The roller cannot be installed once the inner cover is fitted.*

12. Fit a new gasket. Install the inner cover. Using a wrench on the camplate bolt, check that the gears can be shifted. Check that the shifter quadrant clears the cut-out in the inner cover when in the First gear position and Fourth gear position. If it does not, the quadrant and camplate are improperly indexed, and the transmission will not have all gears when completed.

13. Refit the inner cover as previously described.

Lubrication System

Oil Pump

REMOVAL AND INSPECTION

When rebuilding a severely damaged engine, the pump should always be inspected.

1. Remove the timing cover, after taking off the tach drive (if necessary), and disconnect the rocker oil feed pipe at the cover.

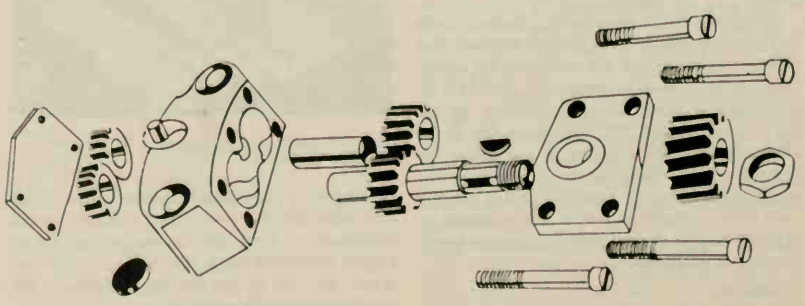
2. Remove the two nuts which secure the pump body and pull off the pump. Remove the oil pump gasket, if fitted.

3. Slowly turn the driveshaft and note any roughness or binding in the movement. The driveshaft should turn smoothly.

4. Grasp the driveshaft gear firmly and push and pull on it. There should be no end-play whatsoever if the pump has oil in it.

5. Check the face of the pump body which mates with the crankcase. Place a straightedge across the stud holes to ensure that the body is not warped. It must, of course, be perfectly flat, or air will be introduced into the oil flow. The mating surface may be lapped flat if necessary after dismantling the pump.

6. Check the conical oil seal on the steel nipple. It must be in very good condition and not deformed. If the seal has been subject to too much pressure, the tapered end will be forced into, and perhaps obstruct, the major oil passage in the timing cover.



Disassembly

1. It is not necessary to remove the pump drive gear to get at the internals, but it may be taken off the driveshaft if desired by taking off the nut which secures it to the shaft and pulling off the gear. Take out the woodruff key also.

2. Remove the four screws in the pump body and take off the brass end plate.

3. Remove the iron plate from the pump body.

4. Using a brass drift, if necessary, tap out the driveshaft. The return side (wide) gear is a close fit on the shaft so the drift will probably be needed.

Oil pump disassembled

5. Tap out the shaft for the idler gears. Remove it from the feed side of the pump.

6. Remove both sets of gears.

Inspection

1. Foreign matter in the gear teeth or chipped or worn teeth will be obvious. Under normal operating conditions, however, and assuming that the engine has received routine attention, there should be nothing wrong.

2. If the engine oil in the tank runs down to the crankcase sump after the bike has been sitting for a short time, the problem may be due to loose pump body screws. Another reason may be excessive wear of the shaft bores in the pump body. There is no remedy for this latter cause, other than replacement of the pump body.

3. Check the sides of the oil pump gears and the pump body for wear caused by contact of the gear sides with the body. If there is evidence of wear, assemble the pump dry, and check that there is a slight resistance to turning the driveshaft. If the shaft turns very freely, excessive clearance between the gears and the body may be the cause. Disassemble the pump, and lap the feed side (narrow gears), on a piece of emery cloth placed on a very flat surface. Assemble the pump, tightening the body screws securely. When turning the driveshaft, a slight stiffness should be noted.

Be careful that lapping is done very gradually.

Repeat the procedure on the return gear side. When the pump is reassembled for checking, do not install the feed gears. The driveshaft should be slightly stiff as before.

Finally, assemble the pump completely, and check that the driveshaft is still stiff. Lubricate the pump with motor oil, and continue turning the shaft. Stiffness should disappear as the shaft is turned.

CAUTION: *Be certain that the pump body is cleaned out thoroughly after each lapping operation.*

Reassembly

1. Clean all of the components thoroughly by washing them in a solvent such as kerosene.

2. Reassemble the gears in their proper positions. The small radius on the return (wider) gears must face the inside of the pump body.

3. Replace the idler shaft and the driveshaft.

4. Place the brass and iron end plates in position and insert the screws, but do not tighten them yet.

5. The end plates must be either perfectly flush or slightly below flush with the edge of the pump body surface which mates with the crankcase. The reason for this should be obvious. There should be just a minimum of play in the end plates which will allow their correct alignment. This is extremely important.

6. Tighten the four screws very securely.

7. Replace the driveshaft key, the drive gear, and the fixing nut.

Installation

1. Oil the pump internals well before installing the pump.

2. Apply some gasket compound to the face of the pump, using it sparingly and being very careful not to get it anywhere near the oil passages. Remember that it will spread along the mating surface when compressed. No gasket compound should be used if a gasket is used between the pump body and the engine as on the 850. A new gasket, however, should also be used.

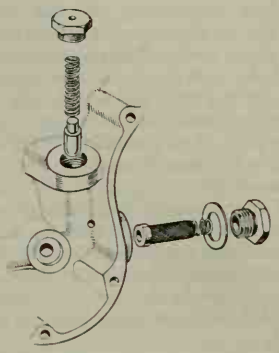
3. Replace the pump on the studs and gradually tighten the two nuts to 15 ft lbs.

System Components

CRANKCASE BREATHER

Latest Commandos have the crankcase breather fitted to the rear of the crankcase (750) or at the timing case (850), and no attention is needed for this type. All others, however, have the breather fitted to, and timed by, the camshaft. The breather mechanism consists of a slotted plate with driving tabs to engage the end of the camshaft, and a spring.

The rotating plate opens and closes openings in a stationary plate and this accomplishes the timing of the breather.



Crankcase breather (early models)

The rotating breather plate must be flat on the mating side and it may be worked on a stone to make it so if necessary. The driving tabs should also be in good condition.

The crankcase breather is connected to the oil tank via a rubber hose. If the engine has been standing a while, oil will usually seep into the crankcase and, when the bike is started, it will come out of the breather for a few moments until the oil pump has completely scavenged the sump. While the motorcycle is in operation, especially at high speeds, the breather will pass oil mist or even pure oil. This is normal; the amounts, however, should not be excessive, as this is indicative of oil remaining in the sump.

OIL PRESSURE RELIEF VALVE

The oil pressure rlief valve is located on the timing case cover just above the junction for the rocker oil feed pipe. The valve has a spring-loaded steel sleeve which is pre-set to open the valve at an oil pressure of 45–55 lbs per square inch (Commando) or 40–50 lbs per square inch (pre-Commando models). Oil passing through the open valve is diverted back to the feed side of the oil pump on Commandos or into the timing case on earlier machines. Although the valve itself does not require attention, it does have a wire mesh filter fitted over one end which is easily cleaned after unscrewing the valve.

Oil pressure relief valve (Atlas)

OIL LINES

1. All external oil lines should be checked periodically for potential cracks or splits, especially at the joints. If the hoses are secured by screw-type hose clamps, these should not be overtightened or they will crack the rubber.

2. The rocker oil feed pipe is especially important. This unit has been known to crack from vibration. It should therefore be inspected closely, especially if engine work has been done, and the pipe moved about. Arrange the pipe so that it does not touch the barrels or head except at the banjo junctions. Alternately, it can be replaced with a flexible hose as used on the latest Commandos.

The sealing ability of the copper washers used at the banjo junctions can be improved by heating them until they are red hot and then allowing them to cool. Be careful when handling after this operation, however, as the washers will be very soft.

Checking the Lubrication System

OIL PRESSURE

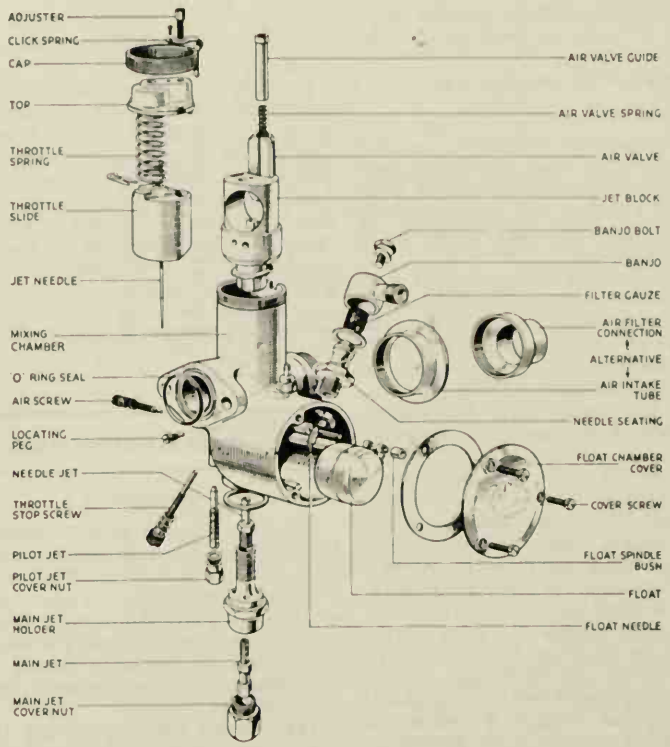
Oil pressure can be readily checked on Commando models with the use of the proper gauge. This is fitted at the rocker oil feed pipe junction and a reading is taken when the engine is at operating temperature. The reading should be 45–55 lbs per square in. at 3,000 rpm.

This method cannot be used for the other models because the rocker arms are fed from the oil return line. The alternative method is to acquire another timing cover. This is then drilled centered with the large oil seal and the gauge inserted. There should be 40–50 lbs per square in. pressure when checked as above, or a minimum of 5 lbs at idle, with the pressure rising with the rpm.

OPERATIONAL CHECKS

If you do not have the proper gauge, the lubrication system can be checked over in some manner by doing the following:

1. Run engine for several minutes until the oil is warm, then check the oil level at the tank and top up if necessary.



2. Take a short ride to thoroughly circulate the oil. Stop and remove the crankcase sump drain plug. No more than one or two pints of oil should come out as this is done. Be sure to replace the correct amount of oil.

3. Loosen one of the banjo fittings at the cylinder head and, with the ignition OFF, kick the engine over briskly several times. Oil should seep from the loosened banjo as you do this, proving that it is being fed to the cylinder head rocker assembly.

4. Let the machine sit overnight. Upon starting, observe the flow of oil at the return line inside the oil tank. There may be a steady stream for a few moments and then a sputtering return of oil as the sump is scavenged.

5. Check the condition of the oil seals contained in the timing cover. Removal and installation of these seals is described in Engine and Transmission.

CAUTION: *Because of a difference in the oil passages, the timing covers found on the Commando are NOT INTERCHANGEABLE with those on earlier machines although they are similar at first sight. Therefore, always be sure that you get the proper timing cover in the event that it must be replaced.*

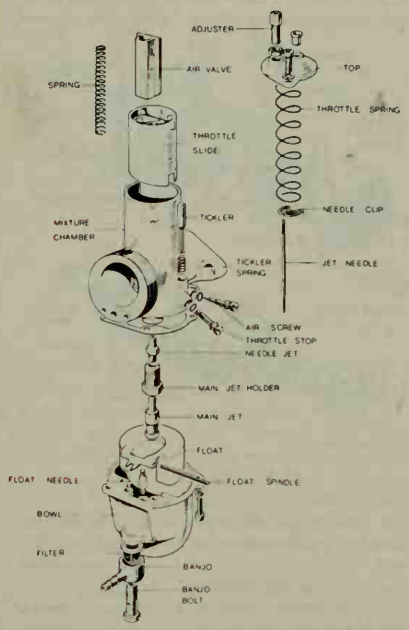
11. Remove the pilot air and throttle stop screws.
12. Remove the locating peg, and shake out the jet block.



Assembly and Installation

1. Assembly is the reverse of disassembly. Use new gaskets, O-rings, and fiber washers.
2. Install the throttle slides in the carburetor bodies before tightening the flange nuts. Tighten slowly and evenly, checking for free slide movement as the nuts are tightened. If the slide begins to stick, the nuts are overtightened, warping the carburetor body.

Removal and Disassembly

1. Remove the gas tank.

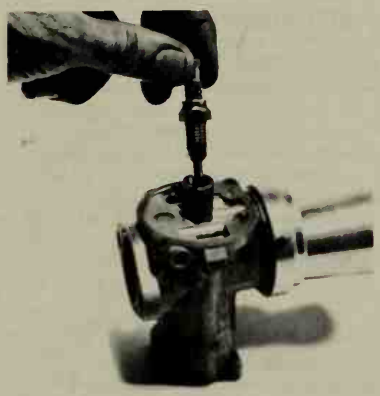
2. Remove the air cleaner.

3. Drain the float bowls if the carburetors are fitted with a plug for this purpose.

4. Unscrew the carburetor caps and pull out the choke and throttle slide assemblies. If it is necessary to remove the slide, remove the choke valve from it, compress the return spring against the carb cap, taking out the needle and clip. Remove the slide after disengaging the cable from it.

5. Unscrew the fuel feed banjo bolt on the float bowl and remove the banjo and filter.

6. Remove the float bowl screws. Hold the carburetor upright and remove the bowl complete with float assembly.



7. Lift out the float, needle, and spindle. The spindle may be a light press fit in the bowl.

Removing the float, spindle, and float needle

8. Unscrew the main jet holder, complete with main and needle jets.

9. Unscrew the pilot jet, if so equipped. Most late models have a bush for pilot metering, which is in the carburetor body and not removeable.

Removing the jet holder complete with main and needle jets

Removing the pilot jet

10. Remove the throttle stop and pilot air screws.

Assembly and Installation

1. Assembly is the reverse of disassembly. Use new gaskets, O-rings, and fiber washers.

2. Be certain that the mounting flange O-ring is firmly in place before the carburetor is bolted to the manifold. Install the throttle slides in the bodies before tightening the flange nuts. Tighten them slowly and evenly, while checking for free slide movement. If the slide suddenly sticks, the body is being warped by overtightening the flange nuts.

3. Do not overtighten the banjo bolt. If too tight, the banjo may be deformed and leak gas.

Modifications

1. Several modifications have been made to the Amal Concentrics since their introduction. Early models had a small mesh-type fuel filter fitted over the main jet. This sometimes hindered the free movement of the float. Since at most places in the U.S., impurities in gasoline are uncommon, and the fuel system is already equipped with filters in the tank and at the carb banjo, the filter on the main jet is really unnecessary and can be removed.

2. A newer type float bowl has been fitted. This has fuel passages for the pilot jet which take the gas near the bottom of the bowl rather than half-way down as before. This was done to assure a positive fuel flow to the pilot jet regardless of variations in fuel level in the float.

3. The jet holder has been changed to thrust the main jet deeper into the float bowl. Once again, the aim was to assure positive fuel flow.

4. The needle jet and needle have both been changed. the newer type needle jet can be readily identified by the small bleed hole at the base of the jet. Looking closer, it can be seen that the jet's metering orifice has been moved from the very top of the jet to the bottom. This has, of course, necessitated the use of a longer needle. This longer needle can be distinguished from the other by the fact that it has two small rings at the very top of the needle (above the clip grooves). The other needle has three rings.

The short needles will not work with the new needle jets or vice versa. Before buying any replacement parts, be sure that they are identical to the parts you have. Of course, it is preferable, if you have an older Concentric, to switch over to the new system completely.

5. A more precise metering of the fuel flow is now obtained with the use of a brass float needle to replace the standard nylon unit. This brass needle has a rubber tip which should form a better seal with the needle seat.

Electrical System

Ignition System

LUCAS K2F MAGNETO

A magneto ignition is used on machines prior to 1967.

The magneto consists of an armature (with a condenser incorporated) rotating in a magnetic field. The armature is driven by chain from the intermediate sprocket. The centrifugal timing advance mechanism is incorporated in the magneto sprocket and is located in the timing case. The contact breaker points are found on the opposite side of the armature, beneath the magneto cover, and are opened and closed as they rotate inside a cam ring.

The high tension leads contact the magneto slip ring via carbon brushes and these brushes are also used for the "kill button" and the magneto ground, the latter being found beneath the screw on the right-side (top) of the magneto.

Service

1. Every 2,000 miles, clean the breaker points and adjust the gap. Refer to "Tune-Up." Check the gap opening at both firing points on the cam ring. If one is greater than the other, it is best to compromise the value.

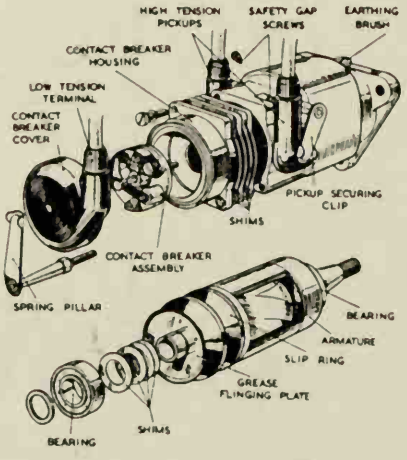
2. Apply a small drop of oil to the breaker point pivot. Also, use some high temperature grease to lubricate the cam ring. Be very careful when using any type of lubricant near the breaker points.

3. Every 5,000 miles, remove the high tension pick-ups, and clean off the carbon brushes. The brushes are mounted on springs and should slide freely in the pick-ups. There must be at least ⅛ in. of the brush protruding from the pick-up for the magneto to work.

Also clean the ground brush after removing its mounting screw.

4. Stuff a clean rag into one of the pick-up holes and kick the engine over a few times to clean off the slip ring. A good deal of oil on the slip ring will indicate a defective oil seal which must be replaced.

5. Remove the timing cover and check the play (up and down) of the magneto sprocket nut. If there is more than 0.005 in. of play, the magneto should be disassembled and the bearings replaced or adjusted.



The following procedure is given for either mechanical (i.e., bearing) or electrical faults:

Removal and Disassembly

1. Remove the timing cover.
2. Remove the magneto points cover.
3. Remove the pick-ups.
4. Unscrew the magneto sprocket bolt and remove the advance mechanism. Remove the two nuts (on studs) and the nut and bolt which secure the magneto to the timing case.
5. Hold the rocker oil feed pipe aside and pull off the magneto.
6. Remove the two safety screws located just by the pick-up holes.

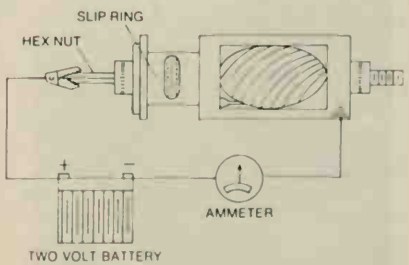
CAUTION: *These screws must be removed before the armature is taken out.*

7. Remove the points; then remove

Lucas magneto

the cam ring, which is a slip fit in the magneto case and must be pulled straight out (with the fingers only). Be careful of the lubricating wicks.

8. Remove the two end cover screws and take off the cover. Be careful of the thin metal shims which may be fitted behind the cover.

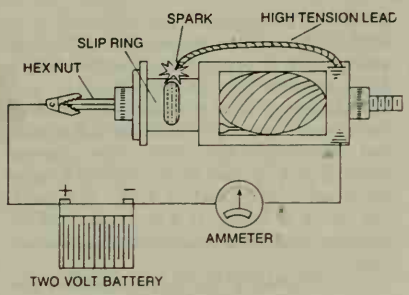


9. Remove the ground brush and pull out the armature.

10. The magneto sprocket-side bearing race is a press-fit in the housing and a fiber washer is fitted around it. An oil seal is beneath the race. If replacement of the race or oil seal is necessary, heat the housing slightly and tap the race out.

Inspection

1. A simple but relatively effective armature test can be made with a two-volt battery. Screw in the hexagon screw which secures the points into the armature, then connect one of the battery leads to this screw, the other to an ammeter. Then connect the other lead of the ammeter to the ground of the armature itself. The ammeter reading should be about four amps. This is a test of the primary winding.



2. To test the secondary winding (this is the high tension side of the circuit) set

Magneto armature low-tension test

up as above. Obtain a length of high tension wire and clamp one end to ground at the armature, supporting the other end from ⅛ to 3/16 in. from the slip ring contact. Make and break the connection at the hexagon screw several times quickly, and observe the spark produced. The high tension spark must be able to jump at least a ⅛ in. gap.

If no spark is produced, the armature

Magneto armature high-tension test

windings or the condenser is defective. Replacement of the complete assembly is the only practical solution.

3. On occasion, a magneto will go intermittent, producing spark on one cylinder, or severe misfiring while running. This is sometimes due to a broken wire within the windings. This cannot be rectified and the armature should be replaced.

4. Magneto bearings are adjustable by removing the thin metal shims from behind the end cover until the end play of the shaft is within acceptable limits.

When the last of these shims have been removed, there is still some possibility of adjustment by adding shims behind the inner races on the armature shaft. However, it requires a special tool to remove or replace the inner races.

Excessive bearing play is most often the result of the drive side outer bearing race, which rides on a rather flimsy fiber insulator, becoming loose.

The ball bearings themselves are held on the inner races by a standard cage. They can be easily removed by simply pulling off by hand as the cage is somewhat flexible.

5. The timing advance mechanism should be inspected. Check for worn sprocket teeth. The two springs which control bob-weight movement should have from 12–14 oz of tension at 1/16 in. extension.

If the machine has been idle for some time, bathe the advance mechanism in light penetrating oil to assure free movement of the weights.

If the timing cover has not been removed, the efficiency of the timing advance mechanism can be checked by moving the points into the full advance position, when closed. They should return immediately to their normal position when released. If they do not, the advance mechanism is sticking (perhaps the drive chain is too tight) or one or both of the springs may be broken.

Assembly

1. If the sprocket-side bearing race has been removed, fit a new oil seal. Bend the tabs of the insulating washer so that the washer fits the bearing race. Install the washer and press in the race.

2. Lubricate the bearings with a good grade of high temperature grease before installation.

3. Refit the armature, the ground brush, safety screws, and end cover.

4. Replacethe point's cam ring.

NOTE: *As on removal, the cam ring must slide directly in. It must be done by hand. Do not force the ring into place. Note that the ring is notched to align with a small stud in the end cover.*

5. Replace the points assembly. The backing plate is "keyed" and must align with its slot. Replace the hexagon screw.

6. Replace the complete magneto and place the timing advance mechanism on the armature shaft.

7. Adjust the magneto drive chain and set the ignition timing.

CAPACITOR IGNITION

The capacitor ignition system utilizes a dual-point and dual-coil set-up. A capacitor is wired in parallel with the battery and should provide spark even if the battery condition is low.

To check each of the components in the event of a lack of spark, follow these procedures:

Ignition Coils

1. The ignition coil for each cylinder can be checked by inserting a nail or other suitable conductive object into the spark plug cap and holding this about 1/8 in. away from the cylinder fins while kicking the engine over briskly. A spark should be able to jump the gap.

2. Pre-1970 and some 1972 models use the Lucas 17M12 coil. The primary winding can be checked by connecting an ohmmeter across the low tension terminals (white and black-white leads or white and black-yellow leads). The reading for the 17M12 coil should be 3.3–3.8 ohms.

Late models are equipped with 17M6 coils. These are 6 volt coils, although the rest of the electrical system remains 12 volt. The 17M6 coils have a ballast resistor wired in series. Resistance for the primary winding is 1.7–1.9 ohms.

The ballast resistor can be tested and should yield a value of 1.8–2.0 ohms.

Condensers

To test the condensers, turn on the ignition and take voltage readings across each set of contact points when open. If no reading is obtained, the condensers have broken down and must be replaced.

If a voltage reading is obtained but there is noticeable arcing and pitting of the ignition points, the condensers should be replaced.

On 1970 models, the condensers are fastened to the coil clips and are reached from beneath.

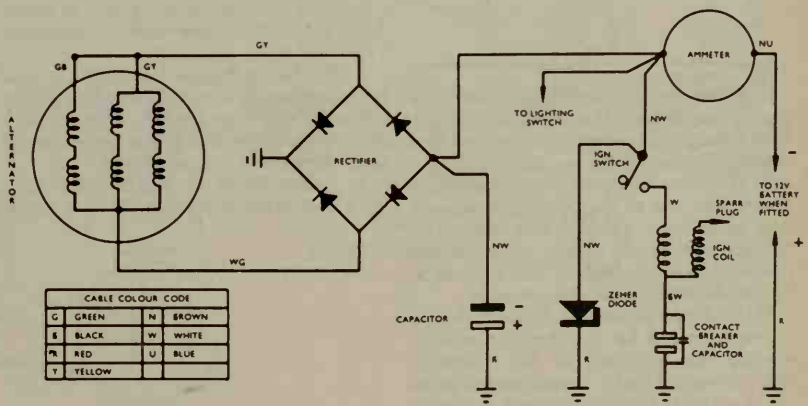
On 1971 and later models, the coil assembly must be removed and then the condenser pack (2 screws and nuts). Remove the rubber cover which will reveal the condensers mounted individually to the base plate.

2MC Capacitor

The large Lucas 2MC capacitor is mounted in a coil spring secured to the frame.

1. The capacitor should be checked periodically; this can be done by simply disconnecting the battery (tape up the leads to avoid the possibility of a short circuit). The machine should be able to start and run normally. The lights should still work, although they may be dim at low revs, getting brighter as engine speed increases.

2. The capacitor should be mounted with the terminals downward. The single terminal (marked with a red dot) is positive and the double terminal is negative. The terminals are also different sizes, making reversal of the connections almost impossible.



NOTE: *If, by some accident, the connections are reversed, the capacitor will be ruined.*

3. The capacitor can also be checked by removing it from the machine and connecting a fully charged 12 volt battery across it, leaving it this way for about five minutes. Then, disconnect the battery and let the capacitor sit for another five minutes. At the end of this time, a DC voltmeter connected across the capacitor terminals should give a reading of at least 8 volts.

The capacitor has a limited storage life of approximately 18 months at 68° F. or 9 to 12 months at 86° F. Therefore, it would be wise to check the condition of the capacitor regularly.

Charging System

IMPORTANT: *All models are equipped with a 12 volt POSITIVE GROUND system.*

Simplified diagram of Commando wiring system

The charging system consists of the alternator, rectifier, zener diode, and the battery itself. 1975 and later models have two diodes.

The alternator produces alternating current by means of a permanent magnet rotor mounted on the left-side of the crankshaft, which rotates within a stationary six-pole laminated iron stator assembly. Three stators have been used and they are easily distinguishable: the RM15 has three leads while the later types RM21 and RM23 have two leads.

The current produced by the alternator is "rectified" (changed to direct current) by the three-plate rectifier.

The amount of charge which the battery receives is determined by the zener diode. This is essentially a variable resistance ("semi-conductor" is the proper term) which automatically raises or lowers the amount of current flowing into the battery according to its condition and needs.

Although the two types of alternator are similar, charging system troubleshooting procedures are provided for each alternator model.

RM15 SYSTEM

There are several types of this model alternator fitted. Nos. 540, 210, and 18 are found on magneto equipped machines, and 047 and 534 on coil ignition machines.

IMPORTANT: *For the results of the following tests to be valid, the battery must be in good condition and more than half charged.*

Test the system as a whole first by assuring that the battery is receiving the proper charge:

1. Be certain that all electrical connections are clean and tight.
2. Disconnect the 2MC capacitor if fitted.
3. Disconnect the battery negative cable and connect a DC ammeter between the cable and the negative terminal of the battery.
4. Start the engine and run it at 3,000 rpm.
5. Observe the ammeter readings at each of the lighting switch positions.

Switch Position	Alternator RM15 Type	
	540, 210, 18	047, 534
Off	2.75 amps	2.75 amps
Park Light	2.0	1.5
Headlight	2.0	1.5

6. If the readings are higher than those given, the battery may be overcharged. This would most probably be caused by a defective zener diode.
7. If the readings are lower than those given, any one of the other components may be at fault. Perform the test again, but disconnect the diode cable. If the readings become higher, the fault is in the diode, which must be replaced.

If the diode cannot be faulted, the alternator should be checked for voltage output. This requires an AC voltmeter (20 volt range) and a 1 ohm resitor capable of carrying 20 amps without overheating.

1. Disconnect the three alternator leads at the snap connector.
2. Connect the resistor in parallel with the AC voltmeter and check the voltage output between the alternator leads. The following values are the minimum acceptable for an alternator in good condition, with the engine turning 3,000 rpm.

Voltmeter and Resistor connected between leads	Alternator RM15 Type	
	540, 210, 18	047, 534
White-Green and Green-Black	4.0v.	4.0v.
White-Green and Green-Yellow	6.5	6.5
White-Green and Green-Black*	8.5	9.0
Each lead and ground	0.0	0.0

* With Green-Yellow connected to Green-Black

The following conclusions can be drawn from the test results:

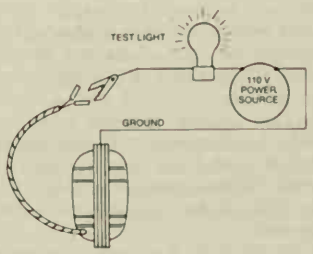
A. If all readings are low, the rotor has become demagnetized.

B. If any individual readings are low, a single coil or coils are short circuited.

C. Zero reading indicates that individual coil or coils are open circuits.

D. Any voltage reading obtained with the voltmeter and resistor connected to any lead and ground indicates coil or coils internally grounded.

If the alternator tests out okay, the trouble is probably the rectifier. This component is best checked by replacing it with a known workable rectifier. A bench test is given later however.



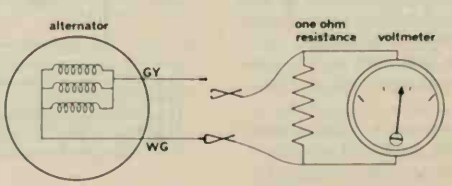
RM21 SYSTEM

IMPORTANT: *Before the following tests are carried out, the battery must be in good condition and close to a full state of charge.*

1. Leave the cable connections to the rectifier in place; connect the negative lead of a DC voltmeter (20 volt range) to the center terminal of the rectifier, and the other lead to a ground on the frame or engine. The voltmeter should read battery voltage at this point, if the proper connections are in order.
2. Start the engine and run it at about 3,000 rpm. The voltmeter should register 14.4–16.4 volts.
3. If the voltmeter reading is the proper value, all components are working properly and any trouble with battery charging must be due to the battery itself or to the battery connections.
4. If the voltage reading is higher than the given value, the zener diode is faulty and must be replaced.
5. If the voltage reading is lower than normal, the alternator, rectifier, diode, or 2MC capacitor can be at fault.
6. If the voltage reading is lower than the given value, perform the test again, but disconnect the diode. The voltage reading should read higher than the regulated value of 14.4–16.4 volts. If it does, the diode is faulty. If it does not, the alternator, rectifier, or capacitor may be at fault.
7. Disconnect the 2MC capacitor and repeat the test. If the voltage reading reaches the normal value, the capacitor is faulty and must be replaced. If it does not, the trouble must be in either the alternator or the rectifier.
8. Test the voltage output of the alternator. Disconnect the two leads at the snap connector and connect an AC voltmeter (20 volt range), with a 1 ohm resistor wired in parallel with it, to the two alternator leads.
9. Start the engine and run it up to about 3,000 rpm. The voltmeter should give a reading of 9 volts if the alternator is satisfactory. If it does, the rectifier is at fault and must be replaced. If it does not, further checks can be carried out to determine the cause of the alternator failure.

The alternator may fail due either to a short or an open circuit in the stator windings or a demagnetized rotor.

1. Connect a 110 volt AC 15 watt test light circuit between the alternator leads (one at a time), and the stator laminations. If the light goes on, there is a short circuit in the windings.



Testing the stator for short circuits

2. It is extremely difficult to carry out a test for an open circuit, so at this point the best thing to do is to fit a replacement rotor and see if this cures the problem. If it does not, the stator is at fault. Since it is plastic-encapsulated, no service is possible and the stator must be replaced.

RM23 SYSTEM

1. Needed for an alternator test are an AC voltmeter and a one-ohm resistor.
2. Disconnect the two alternator leads at the snap connectors and hook up the AC voltmeter across them. Connect the resistor in parallel to the alternator leads.

Testing RM21 alternator voltage output

3. Start the engine and run it at 3,000 rpm. The voltmeter reading should be nine volts.

4. If the output is low, the rotor may be becoming demagnetized. The best check is by substitution. If the reading is zero, the stator probably has a broken wire and must be replaced.

System Components

RECTIFIER

A 12-volt test light is needed to carry out the rectifier test.

1. Disconnect the leads and remove the rectifier from the machine. Take care not to disturb the bolt and nut which hold the rectifier plates together as they are set at the factory and disturbing them will affect rectifier output.

2. Assume that the three rectifier plate terminals are numbered 1, 2, 3, and the mounting stud is No. 4.

3. With the test light, check for continuity across the terminals using the following pairs of connections: 1-2, 1-4, 3-4, and 2-3.

4. In each case, reverse the test light leads and again check for continuity.

5. Reading should be as follows: For each connection, there must be continuity in one direction only. If there is no continuity in either direction, or if there is continuity in both directions for one or more of the connections, the rectifier is defective and must be replaced with a new one.

ZENER DIODE

The zener diode accomplishes the function of a voltage regulator. When the voltage across the battery terminals reaches 13.5–15.5 volts, the diode becomes conductive and routes excess voltage to ground.

It is important that the diode always be securely mounted to the heat sink and that the heat sink is firmly attached to the frame. Also, the heat sink should be placed in the cooling airstream.

To test the zener diode, a DC ammeter and voltmeter are needed.

NOTE: *When carrying out this test, the battery must be in good condition and have a full charge. Otherwise the test results will not be valid.*

1. Disconnect the zener diode lead and connect the positive wire of the DC ammeter to the diode and the negative ammeter wire to the lead.

2. Connect the voltmeter across the diode terminal and ground (positive to ground).

3. Be sure that all lights and accessories are OFF.

4. Start and run the engine; note the following meter readings: when the voltmeter reads 12.8 volts or less, the ammeter should show zero current flow. When the ammeter shows 2.0 amps flowing, the voltmeter should read 13.5–15.5 volts.

5. If readings do not conform to the above specifications, replace the zener diode.

ALTERNATOR

The alternator requires no maintenance as such, but the following points should be noted:

1. Clean off the rotor and the stator poles from time to time removing any foreign matter, metal particles, etc.

2. Make sure that the rotor is not worn or scored from contact with the stator poles.

3. There must be no contact between the rotor and the stator poles. Ideally, there should be an even gap between the two all around the rotor. This can be checked with a feeler gauge. Clearance should be about 0.010 in. The position of the stator can be altered by using shim washers behind it placed on the housing studs.

4. Before tightening the stator mounting nuts, place an appropriate spacer around the rotor, then place the stator on its studs. Tighten the nuts with the spacer in place. This will help centralize the stator.

Starter Motor

1975 and later models are equipped with a Prestolite starter motor.

Removal

1. Disconnect the starter high-tension lead.

2. Remove the three screws from the primary chain cover flange and remove the starter noting the O-ring.

Disassembly

1. Mount the starter in a suitable vise.

2. Before disassembly, note that the end covers are marked in relation to the body itself and must be properly lined up when assembling.

3. Remove the two through-bolts.

4. Tap the end of the armature with a platic mallet or the like until the opposite side end cover begins to come off. Stop when the cover has moved about ⅛ in. At this point, hold the armature while attempting to pull off the end cover.

5. After this end cover is removed, tap the brush side of the armature to remove the drive-side end cover.

6. Remove the armature from the starter body, noting that the brushes will spring out as the armature is withdrawn.

Inspection

1. Check the armature bushings for cracks or signs of wear. The drive side bushing can be tapped out with a drift, if replacement is needed, after prying out the oil seal.

The brush-side bushing is removed with a tap.

In both cases, removal and installation can be facilitated by heating the end covers gently.

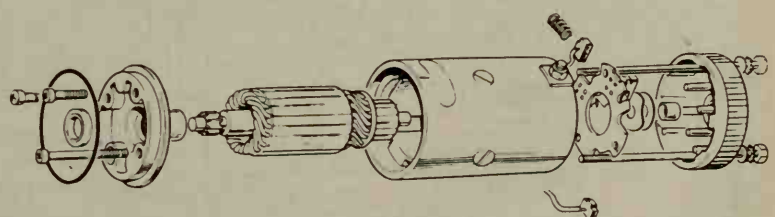
2. Clean the armature commutator in a solvent to remove any residue or carbon dust.

3. With a continuity tester, check for continuity between each of the commutator segments. All segments must show continuity, or the starter armature must be replaced.

4. Check for continuity between the armature core and the commutator. There must be no continuity here. If there is, replace the starter armature.

Assembly

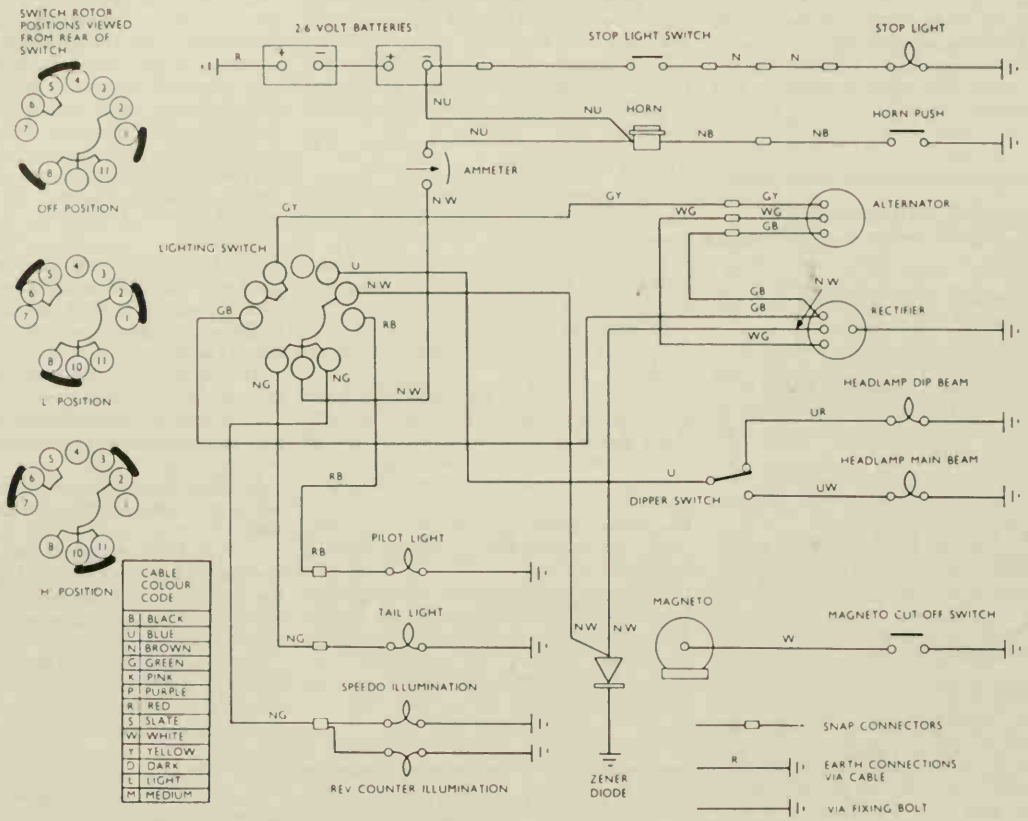
1. Assembly is the reverse of the disassembly procedure.



2. Before assembly, apply a light coat of molybdenum disulphide grease to each armature bush.

3. After fitting the armature into the body, install the spring shim and thrust washer. Note that the spring shim is closest to the armature.

4. When assembling the end caps, be sure to line up the marks. Use thread locking compound on the through-bolts and torque them to 8 ft lbs. Check that the armature turns easily. Some resistance will be imparted by the brushes which bear against the commutator.



Installation

Be sure that the O-ring is in place when installing the starter.

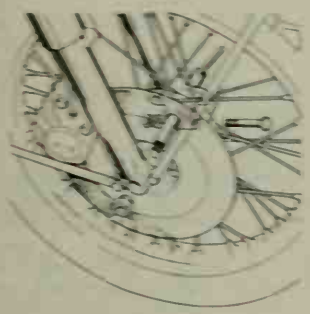
Wheels

FRONT (DISC BRAKE)



1974 and Earlier

REMOVAL AND DISASSEMBLY

1. Support the front wheel of the machine about six inches off the ground by placing a wooden box or wire milk basket beneath the engine.

2. Remove the axle nut; loosen the axle clamp nut on the left fork tube.

3. Slip a suitable bar or a philips screwdriver into the hole in the axle and, supporting the wheel with one hand, pull out the axle.

Removing the front wheel (disc brake)

4. Pull the wheel forward, to disengage the disc from the pads, and take it away from the forks.

5. Take off the wheel bearing dust covers to avoid the risk of losing them.

6. Place a ¼ in. thick spacer of either wood or metal between the brake pads, to prevent their accidental ejection.

7. To disassemble the wheel hub, if this is felt to be necessary, use a peg wrench to remove the lockring from the left-side of the wheel. If a peg wrench is not available, the ring can be threaded out by tapping, very carefully, at one of the peg holes with a suitable punch, and unscrewing the ring in this manner.

If the ring resists removal, the hub may be heated very gently with a low flame.

8. Remove any spacers and seals on either side of the hub. Note the order of assembly to facilitate installation.

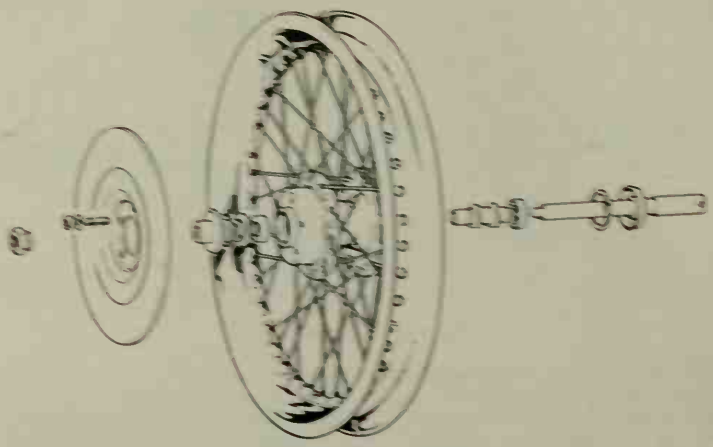
9. Insert a drift into the right-side of the hub and use it to pry the spacer tube out of the way as far as possible to expose the inner race of the left wheel bearing. Use the drift to drive out the bearing by tapping against the inner race. It will be necessary to move the spacer tube back and forth to tap on both sides of the race. If necessary, the hub may be heated with a rag which has been soaked in boiling water.

10. Remove the spacer tube; then drive out the remaining bearing in the same manner.

ASSEMBLY AND INSTALLATION

1. Assembly is the reverse of the disassembly procedure. Pack the bearings thoroughly with a good grade of wheel bearing grease.

2. When driving in the bearings, be sure to drive against the outer race only. Fit the left-side (single-row) bearing first, followed by the lockring, the spacer, and the right-side bearing assembly.



3. Remove the spacer from the brake pads and install the wheel in the forks with both dust seals in position.

4. Grease the axle and insert it from the left-side of the wheel.

5. Refit the axle and tighten the axle nut firmly. Take the support out from under the bike and work the forks up and down several times. Then tighten the axle clamp nut.

CAUTION: *Do not overtighten the clamp nut.*

6. Apply the brake hard several times before operating the motorcycle.

Front wheel assembly (1973 and later)

1973 and Later

REMOVAL AND DISASSEMBLY

1. Support the machine so that the front wheel is off the ground.

2. Remove the axle nut at the left-side of the wheel. Loosen the pinch-bolt on the right fork leg. Lift the wheel slightly and pull out the axle.

3. Remove the wheel. Do not apply the front brake with the wheel removed. To prevent the brake pads from coming out, fit a ¼ in. spacer between them.

Note the dust covers on either side of the wheel which should be placed aside to prevent loss.

4. Remove the circlip from the right-hand side of the hub.

5. To heat the hub to facilitate bearing removal, use a rag dipped in boiling water. The hub should not be heated to more than 100° C (212° F).

6. Insert a drift into the hub and use it to pry the spacer tube out of the way as far as possible to expose the inner race of one of the bearings. Use the drift to drive out the bearing by tapping against the inner race. It will be necessary to move the spacer tube back and forth to tap both sides of the race.

7. Remove the spacer tube; then drive out the remaining bearing in the same manner.

ASSEMBLY AND INSTALLATION

1. Repack the bearings with a good grade of bearing grease.

2. Press the single-row bearing into the right-side of the hub with the sealed side outward. Do not drive against the inner race. Install the circlip, being sure that it is seated in its groove.

3. Install the bearing spacer tube making sure that it abuts the bearing.

4. Install the remaining bearing with the front axle as a drift. Drive the bearing in until it is completely seated. Install the felt seal, spacer, and dust cover on the right-side of the hub.

5. Install the wheel on the motorcycle.

6. After tightening the axle nut, work the forks up and down a few times to center the wheel, then tighten the clamp nut on the fork slider.

7. Check fork action. If it is stiff, loosen the axle nut and the clamp nut and work the forks up and down. Then tighten the axle nut and clamp nut. If the fork action remains stiff, repeat the procedure with the fender bolts loosened as well.

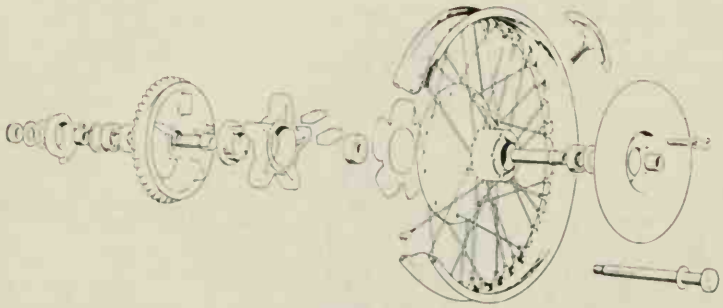
8. Apply the brake hard several times before operation.

REAR (DISC BRAKE)

Removal and Disassembly

The machine must be firmly supported on the center stand. It is recommended that the stand be safety wired in place temporarily so that the machine does not roll forward during the removal procedure.

1. Engage the transmission in First or Second gear. Loosen the lower right-side shock absorber nut and pull it out as far as the circlip.



2. Unscrew and remove the axle from the right-side.

3. Move the wheel to the left and remove the right-side chain adjuster.

4. Lift the caliper assembly up, but keep the pads in contact with the disc, then squeeze the chain adjuster and insert it between the pads. Hang the caliper upside down from the frame hook provided.

5. Lean the machine to the left and remove the wheel.

6. If desired, the sprocket assembly

Rear wheel disc brake assembly

may be removed by disconnecting the chain, detaching the speedometer cable, removing the left-side axle nut, and taking off the assembly.

7. To disassemble the rear wheel assembly, first remove the brake disc.

8. Remove the lockring on the left-side of the wheel.

NOTE: *The lockring is a LEFT-HAND thread.*

9. Remove the small spacer from the right-side of the wheel. The end of the bearing spacer tube will be exposed. Use a soft metal or plastic mallet against the protruding end of the tube to drive out the left-side wheel bearing.

If necessary, the hub may be heated, but to no more than 100° C (212° F), with a rag which has been dipped in boiling water.

10. Use a suitable drift on the left end of the spacer tube and use it to drive out the right-side wheel bearing and oil seal.

11. To disassemble the sprocket hub, remove the bearing circlip and drive out the bearing from the oil seal side.

Assembly and Installation

1. Pack the bearings with grease.

2. Install the disc-side wheel bearing first, driving it straight into the hub with pressure applied to the outer race only. The bearing should be pressed in until it is about 5/16 in. below the lip of the hub. Install the oil seal so that the outer face is flush with the hub lip.

3. Install the spacer tube. Install the left-side bearing. Install and tighten the lockring.

4. Install the spacer into the right-side oil seal.

5. To assemble the sprocket hub, drive in the bearing first. Fit the bearing locating circlip, sharp side outward, making sure that it is seated in its groove. Install the oil seal, metal side out.

6. The remainder of the assembly procedure is the reverse of disassembly.

7. Before riding the machine, apply the rear brake hard several times to line up the brake pads.

FRONT (DRUM BRAKE)

Late models are equipped with a twin leading shoe front brake, while earlier ones feature a single leading shoe unit. In either case, the procedures are similar.

Removal and Disassembly

1. Place the machine on the center stand.

2. Disconnect the front brake cable from the hub.

3. Remove the axle nut, then loosen the axle clamp nut on the left fork leg.

4. Support the wheel to take the weight off the axle, then insert a bar or a philips screwdriver into the hole on the left-side of the axle and pull it out.

5. Watching that the brake anchor clears the slot in the right fork leg, take the wheel out of the forks.

On the P-11, loosen the axle nut, disconnect the brake anchor, remove the axle caps, and remove the wheel.

6. Remove the dust cover on the left-side of the wheel. Remove the brake backing plate assembly from the drum.

7. To disassemble the wheel hub, if this is felt to be necessary, use a peg wrench to remove the lockring from the left-side of the wheel. If a peg wrench is not available, the ring can be threaded out by tapping, very carefully, at one of the peg holes with a suitable punch, and unscrewing the ring in this manner.

8. Remove the felt washer. Remove the spacer, noting that the flat side bears against the wheel bearing.

9. Insert the axle through the right-side of the wheel. A few blows with a soft-faced mallet will drive the right-side wheel bearing against the tube spacer, and this in turn will force out the left wheel bearing.

CAUTION: *The wheel bearing will not usually "pop" out. In fact, it will be difficult in many cases to notice that it has moved at all. Therefore, after hitting the end of the axle once or twice, try taking out the bearing with your fingers. Under no circumstances should you use undue force on the axle.*

10. Take out the axle and insert it into the left-side of the hub. Use the same method to drive out the right-side bearing.

11. Remove the brake shoes from the backing plate by taking out the bolts which secure the fixed end of the shoes (single leading shoe brake), or removing the circlips (twin leading shoe brake).

Assembly and Installation

1. Pack the bearings with a good grade of bearing grease.

2. Press the left-side (single-row) bearing into place after heating the hub gently to facilitate installation. Tap on the outer bearing race only.

3. Replace the spacer, flat side against the bearing, fit the felt seal, and install the lockring.

4. Insert the spacer tube, small end first, into the hub, until it abuts the bearing already fitted.

5. Fit the right-side (double-row) bearing. Be sure that it is fitted squarely into the hub, then drive it home by tapping around the outer bearing race.

6. Fit the thin steel washer (the smaller of the two), the felt washer, and the large steel washer.

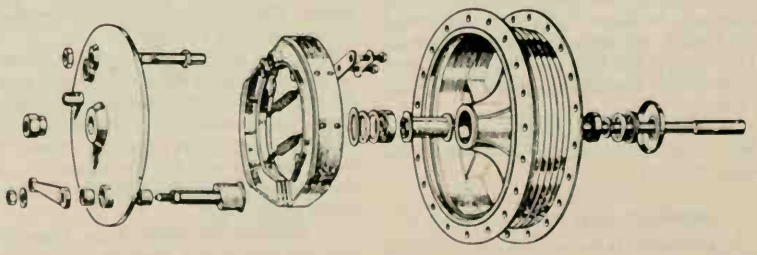
7. Secure the large washer by peening it with a punch across the hub. Replace the dust covers.

8. Replace the wheel, slide in the axle, and replace the axle nut, screwing it down only hand-tight.

9. Apply the handlebar brake lever firmly, and, while maintaining pressure here, secure the axle nut with a wrench. This will serve to centralize the brakes in the drum.

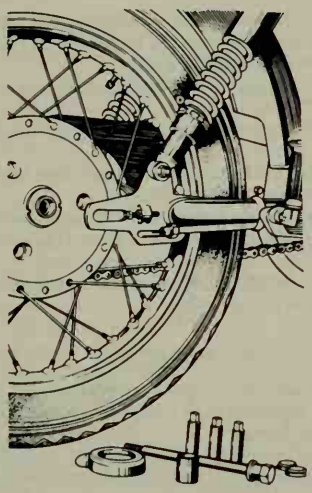
10. Take the bike off the center stand and work the forks up and down several times. Then tighten the axle clamp nut.

REAR (DRUM BRAKE)



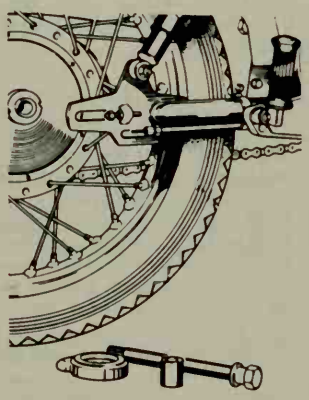
Removal and Disassembly

1. It is possible to remove the rear wheel without disturbing the rear brake, drive chain, etc. The wheel is secured to the brake drum by three sleeve nuts beneath the rubber caps on the rear hub or, as on more recent models, by three tongues on the brake hub. If your machine has the rubber caps, remove them and remove the sleeve nuts with a suitable socket wrench. On P-11 models, disconnect the brake anchor.

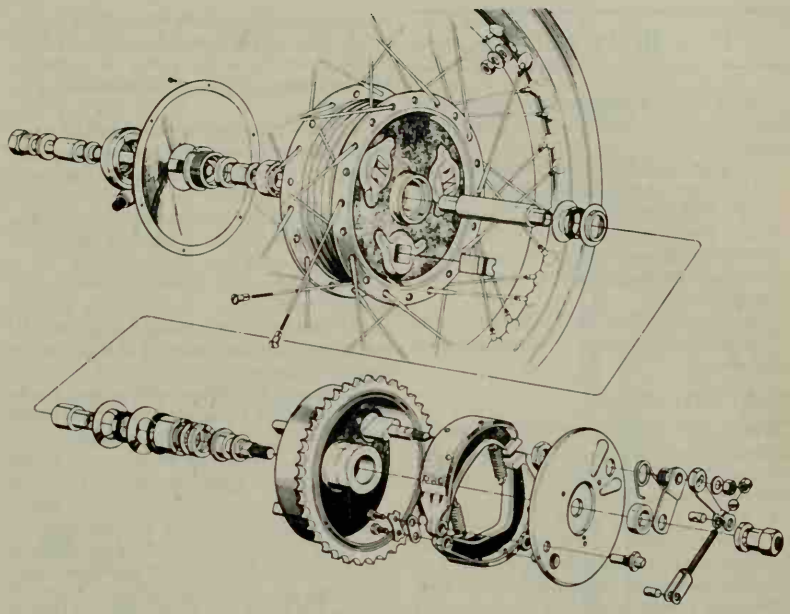


2. Loosen the axle on the right-side of the wheel and pull it out.

3. Remove the spacer on the right-side of the wheel and remove the speedometer drive. It is not necessary to disconnect the cable, simply place the drive mechanism out of the way.



4. Pull the wheel as far as possible to the right-side of the machine, until it is clear of the studs or tongues, then tilt it as necessary to clear the rear fender and pull it out of the machine.



Front hub assembly (pre-Commando)

Removing the rear wheel (pre-1971 models)

Removing the rear wheel (1971 and later drum brake models)

Rear wheel assembly (1971 and later drum brake)

5. If so desired, the rear brake drum can be removed by removing the chain guard (not necessary on late Commando models with the "chopped" chain guard) and disconnecting the drive chain.

6. Remove the axle nut.

7. Remove the rear brake adjuster nut if the brake is rod-operated, or disconnect the brake cable if it is cable-operated.

8. Take out the brake drum and backing plate, taking care not to loose the large spacer. Remove the brake shoes, if desired, referring to "Front Wheel, Drum Brake," above.

9. If it is desired to remove or lubricate the bearing, remove the lockring on the right-side of the rear hub. This ring has a LEFT-HAND thread. Use a peg wrench or a suitable punch and tap the ring to unscrew it. The hub may be heated gently in the vicinity of the ring if it resists removal.

10. Take out the felt washer, being very careful with this item as it is very fragile; also remove the spacer.

11. To the axle, fit the large lockwasher with which it is equipped and the large spacer found between the speedometer drive and the swing arm.

12. Insert the axle into the left (brake) side of the wheel and use a soft-faced mallet to strike the axle smartly once or twice. You will feel the brake side bearing give until it bears against a shoulder in the hub. It will have pushed the right side bearing out by an equivalent amount. stop at this point and withdraw the axle.

13. Obtain a short piece of steel tubing with a diameter just slightly smaller than the inside diameter of the bearing. The front wheel axle is suitable for this purpose. Insert the tubing, or the threaded end of the axle, into the brake side bearing, center it, and tap lightly until the right side bearing is driven out. The axle will bear against the spacer inside the hub, which in turn will serve to drive out the right-side bearing.

14. Take out the spacer, if it is still in place, and remove the drift you used. Insert the rear axle (and spacer), into the right-side of the wheel. Carefully center it on the brake side bearing and drive this bearing out with a couple of blows on the end of the axle with a soft-faced mallet. The steel cup washer, felt washer, and thin steel washer will come out with the bearing.

Inspection

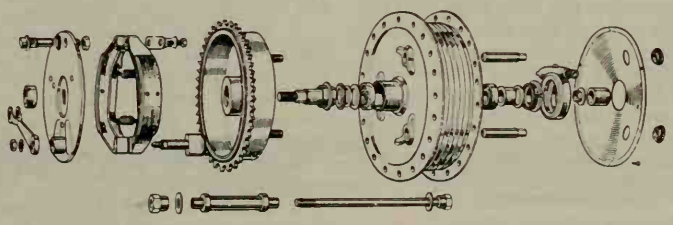
1. In 1971, an additional bearing was introduced in the rear brake drum. This bearing should be inspected and lubricated at the same time as the wheel bearings.

2. The three tongues on the brake assembly which drive the wheel must be inspected for security. The tongues are brazed into the brake drum. Note that the brazing material must have run all around the tongue bosses when viewed from inside the drum.

Assembly and Installation

1. Fit the right-side (single-row) bearing into the threaded side of the hub.

2. Fit the tube spacer from the left-side with the long end inserted into the single-row bearing.



3. Refit the spacer, the felt washer, and the lockring on the right-hand side of the hub and tighten the lockring. Remember, it has a left-hand thread.

4. Replace the brake side bearing and drive it home using the rear axle and spacer as on removal.

5. Fit the thin steel washer, the felt washer, and the cup washer in that order. Peen the cup washer against the hub with a suitable punch.

6. The rest of the assembly is a reverse of the disassembly procedure. Be sure that the speedometer drive is correctly engaged in the slots of the lockring before tightening the axle.

Also, apply the rear brake pedal hard, then tighten the axle nut (left-side), while holding the brake pedal on to centralize the brakes in the drum.

Disc Brake Service

The following precautions should be observed when working on the disc brake system:

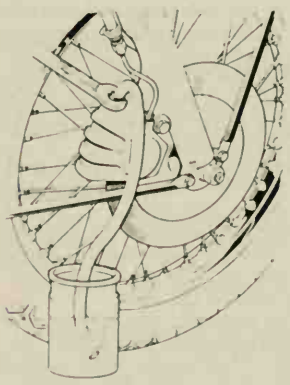
a. Use only DOT 3 brake fluid;

b. Never reuse brake fluid drained or flushed from the system. Never use brake fluid from an old or unsealed container. Brake fluid is "hydroscopic" (water-absorbing), and is easily contaminated;

c. Do not allow brake fluid to contact painted surfaces as it can remove the finish.

FRONT DISC BRAKE

Every 18 months or 24,000 miles (whichever comes first), the hydraulic system should be drained and refilled with fresh brake fluid.



1. Attach a length of plastic tubing to the bleeder screw of the hydraulic unit (as illustrated), placing the other end in a suitable container, assuring that the end of the tube is immersed in a small amount of new brake fluid.

2. Turn the bleeder screw one-half turn.

3. Apply the brake slowly, allowing it to return unassisted. Allow a slight pause between each brake application. Be sure that the master cylinder is kept full by adding the new fluid as needed.

4. When clean fluid, which is completely free of bubbles, emerges from the plastic tube, the flushing operation is complete.

5. Apply the brake lever hard, hold it on, and tighten the bleeder screw.

Bleeding the front disc brake

6. Refill the master cylinder to the correct fluid level (one half inch below the top of the cylinder).

In the event of excessive lever travel or a spongy feel in the front brake, the system must be bled, after first determining the cause of the malfunction.

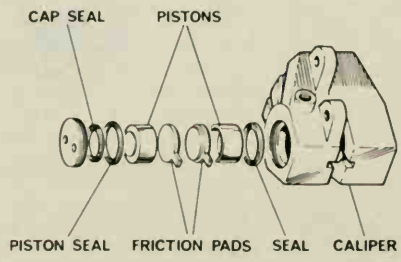
The bleeding procedure is identical to that for flushing the system as described above, except that it is only necessary to continue the process until the bubbles cease to come out of the plastic tube.

Friction Pad Replacement

1. Remove the front wheel.

2. Rotate the friction pads slightly and remove them from the caliper.

3. The pads should be inspected for uneven or excessive wear or scoring. Minimum acceptable thickness is 1/16 in. (1.5 mm).



4. Clean the pad with the aid of a soft brush. Do not use any solvent or wire brush for removing deposits from the pads.

5. Smear the piston faces and brake pad recesses lightly with disc brake lubricant.

6. Remove the master cylinder cap and bellows seal.

7. Press the pistons back into the caliper, observing the brake fluid level in the master cylinder.

8. Smear the edges of the pad backing plate with disc brake lubricant and press the pads against the pistons.

Disc brake caliper assembly

9. Replace the front wheel and spin the wheel while applying the brake lever several times.

10. Check the master cylinder fluid level.

NOTE: *If new pads are fitted, they must always be fitted in pairs. Also, the correct pad must be obtained depending on whether the machine is equipped with cast iron, or stainless steel, discs. The latter is identifiable by the part number (063464) stamped on the outer rim. When new pads are fitted, they must be "broken in" for at least 50 miles by avoiding hard application of the brake.*

Caliper

If the pistons will not move freely in the caliper, this unit should be disassembled and inspected.

Disassembly

1. Loosen, but do not remove, the caliper end plug.

2. Remove the two caliper bolts and washers and swing the caliper clear of the fork leg, watching for the brake hose.

3. Remove the two friction pads from the caliper.

4. Clean the outer ends of the pistons and the caliper body with alcohol.

5. Place a can below the caliper to catch the brake fluid. Apply the brake lever, and the inner piston will come out into the pad cavity and the fluid will be released.

IMPORTANT: *If the piston is seized, the entire caliper assembly must be replaced.*

6. Loosen the lower brake pipe junction nut and separate the pipe from the caliper.

7. Remove the caliper end plug which was previously loosened and drain out the remaining fluid.

8. Remove the piston from the caliper.

9. Remove the pressure seal from the outer bore.

CAUTION: *Take extreme care not to damage the seal grooves.*

10. Remove the inner piston through the outer cylinder bore. Then remove the pressure seal from the outer bore.

11. Mark the friction pads for position ("inner" and "outer").

Inspection

1. Clean the pistons, caliper bores, and seal grooves with ethyl alcohol or clean brake fluid.

2. Examine the pistons for corrosion, wear, scoring, or unevenness of the thrust faces. If there are any irregularities present, the piston must be replaced.

3. Check the caliper bores for corrosion, scratches, abrasion, or damage to the seal grooves.

Assembly

1. Coat new pressure seals with disc brake fluid and insert the first seal into the inner bore with your fingers, making sure that it is correctly fitted.

2. Coat the inner piston with the brake fluid and insert it into the inner cylinder bore (closed end first) after passing it through the outer bore. Let the piston protrude about 5/16 in. from the inner bore.

3. Fit the other pressure seal to the outer bore groove.

4. Insert the other piston into the other bore (open end first) until about 5/16 in. protrudes from the inner mouth of the bore.

5. Replace the end plug. A new O-ring must be fitted.

6. Fit the friction pads and replace the caliper assembly on the fork leg.

7. Torque down the end plug to 26 ft lbs.

8. Examine the fitting of the metal brake fluid pipe for distortion, cracks, or other damage. Fit the pipe into the caliper. Screw down the junction screw until the metal pipe is just lightly seated.

CAUTION: *Tighten the junction nut with a wrench no more than 60°. This is VERY important.*

9. Loosen the bleed nipple one full turn and connect a bleed tube to it as described earlier in this section. Fill the master cylinder with the recommended brake fluid.

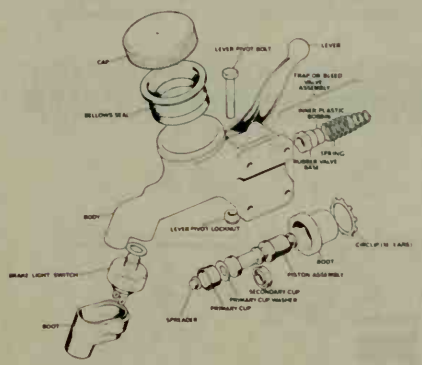
10. Work the brake lever until the fluid begins to flow through the bleed tube. Be sure to keep the master cylinder topped up or air will be drawn into the lines. Hold the brake lever on while adding fluid.

11. When fluid, without bubbles, begins to flow through the bleeder tube, hold the brake lever on and tighten the bleed nipple.

12. Check the brake for sponginess and examine the system for leaks. Recheck the master cylinder fluid level, and fill it up as necessary.

Master Cylinder

Removal and Disassembly



1. Disconnect the brake light switch and lift off the rubber switch cover which exposes the hose junction.
2. Disconnect the hose.
3. Remove the four screws and take off the master cylinder assembly.
4. Remove the reservoir cap and bellows seal. Also remove the brake light switch.
5. Remove the brake lever bolt and the brake lever.
6. Carefully pry out the boot circlip, then remove the boot complete with piston and secondary cup.
7. Remove the primary cup washer, primary cup, spreader, spring, and valve assembly. These parts may be removed by GENTLY tapping the edge of the master cylinder assembly on a wooden block.

Inspection

1. Clean the master cylinder and piston in brake fluid or methyl alcohol. Inspect the cylinder body for wear of the piston bore.
2. Make sure that the two ports in the reservoir chamber are clear.
3. Inspect the hose junction for cleanliness.
4. Check the body of the master cylinder assembly for any cracks or fractures, especially in the area of the lever bolt.
5. Check for wear of the piston thrust face.

Assembly

1. Clean all parts and lay them out for reassembly, referring to the exploded diagram.
2. New primary and secondary cups MUST be fitted. Saok the new cups in hydraulic brake fluid for fifteen minutes, kneading them occasionally.
3. Take the secondary cup and place its non-lipped side against the ground "crown" diameter of the piston. Work the cup over the crown by hand, down the piston body, over the shoulder, and into its groove.
4. Fit the boot over the piston (open end toward the piston crown) and ensure that the boot upper end is fitted into the piston groove. Oil the piston assembly lightly with brake fluid.
5. Assemble the valve to the spring. Make sure that the inner plastic bobbin is seated in the valve base and that the plastic spreader is pressed securely into the spring.
6. Fit this assembly into the master cylinder, valve end first, holding the master cylinder bore vertical.
7. Place the primary cup into the bore (open end inward), the washer (convex side upward toward the open end of the cylinder bore). Lightly oil the mouth of the cylinder bore.
8. Take the master cylinder assembly in your left hand and insert the piston assembly into the bore.
9. Apply a gentle rotary action to the piston assembly with your right hand, at the same time maintining pressure downward against the valve spring assembly.
10. Be sure that the lip of the secondary cup enters the bore freely. When the piston has entered the bore, use your left thumb to hold it there and press the lower boot shoulder in.
11. Maintain pressure on the piston and slide the brake lever into position, engaging the thrust pad. Replace the lever bolt.
12. The remainder of the assembly procedure is the reverse of disassembly. Bleed the system as previously described.

Front disc brake master cylinder assembly

REAR DISC BRAKE

1975 and later models are fitted with an hydraulic disc rear brake. Service procedures for the brake system components are the same as described for the front disc brake.

Adjustment

To adjust the rear brake pedal, loosen the locknut which bears against the brake rod clevis and turn the rod to adjust the pedal.

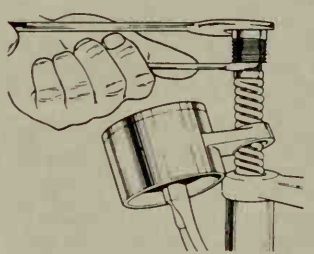
CAUTION: *Do not loosen the two locknuts at the opposite end of the rod since this will alter the master cylinder piston stroke. This adjustment is made at the factory.*

Front Forks

The fork legs can be removed individually, leaving the steering column in place, or the entire assembly can be taken off at once. The first procedure is given below.

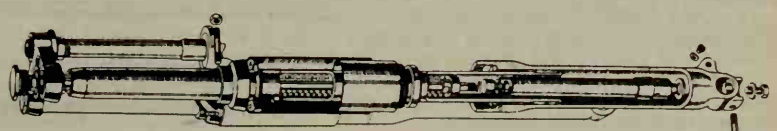
REMOVAL AND DISASSEMBLY

1. Support the front wheel well off the ground. Remove the front wheel, as previously described, and also remove the front fender.
2. Remove the drain plugs at the bottom of the sliders to drain the oil.

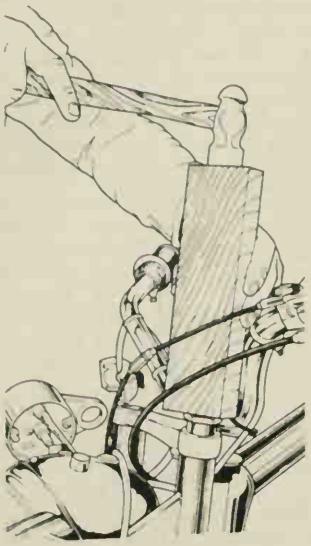


On 1974 and earlier disc brake models, remove the hydraulic system completely after placing a ¼ in. spacer between the brake pads.

On 1975 and later models, the brake system cannot be removed completely. Drain the system completely by means of a tube attached to the bleeder screw. Disconnect the brake line at the junctions. Remove the caliper from the slider. Remove the master cylinder.



"Slim-line" type forks (Commando)



3. Loosen the filler cap nut at the top of the fork leg until it is clear of the threads in the triple clamp. Then use a thin wrench to loosen the locknut on the damper rod so that the capnut can be removed from the rod. It may be necessary to push up on the fork leg to raise the damper rod enough to gain access to the locknut.
4. Loosen the clamp nut or allen bolt on the lower triple clamp.
5. A sharp downward yank on the fork leg should free the upper end from the upper triple clamp. If necessary, the capnut can be threaded a few turns into place. Then, a sharp blow with a soft-faced mallet should be enough to free the fork leg.
6. Repeat the procedure with the other fork leg.
7. On Scrambler models, remove the external fork springs.

Removing the fork cap nut from the damper rod

Roadholder forks (Atlas)

Freeing the fork tube from the upper triple clamp

8. Remove the rubber fork gaiter, if fitted, or the rubber dust cover.

9. Remove the bolt and washer at the very bottom of the fork slider (a thin-walled socket is needed to reach this bolt) and take out the spring and damper assembly from the top of the fork tube.

A fiber washer is placed at the bottom of the damper tube and may remain in the fork slider.

10. The alloy fork slider has an extension screwed into it, the length and type of the extension depending on the model of the machine. To remove the slider, the extension must be taken off first. Most models have holes for the appropriate peg wrench on the extension and, if this tool is available, removal is a simple matter. If the peg wrench is not to be had, however, an alternative method is to fasten a heater hose clamp to the extension (at the bottom portion of the long chrome plated extensions, if that is what you have); vise-grip pliers can then be locked on to the screw assembly of the clamp and used to turn the extension.

Unscrew the extension all the way, then take off the slider from the bottom of the fork tube.

11. Remove the extension from the top of the fork tube and also remove the oil seal, paper washer, and flanged bush (bronze), in that order, from the top of the tube as well.

12. The bottom bush (steel) is held in place by a circlip and can be removed after the circlip is taken off.

13. The damper tube can be disassembled on Atlas and Commando models, if desired, by taking off the nut at the top of the rod, the spacer, and the long spring.

14. Insert a suitable rod through the holes in the damper tube to keep it from turning, and unscrew the damper tube cap nut. Removing the nut at the bottom of the rod will allow the slotted washer, cup, and crosspin to be removed.

15. On Scramblers, the damper tube is disassembled by taking off the bottom nut, the brass seat for the damper valve, the damper valve itself, and the crosspin. Remove the circlip and take off the plunger sleeve.

NOTE: *The oil groove is closest to the bottom of the rod when installed.*

INSPECTION

1. Remove any rust from the exterior of the fork tube with emery cloth. This is most likely to form beneath the headlight supports.

2. Make sure that the inside of the fork tube is clean and smooth.

3. The flanged (bronze) bush should be a close but free sliding fit on the fork tube. It must be replaced if excessive clearance is noticed.

4. The oil seal and paper washer should be replaced with new items if possible. The rubber lip of the seal must be free of cracks, signs of age, dirt, or corrosion.

5. Check the damper tube and assure that it is free of corrosion, foreign matter, and has a smooth interior surface.

6. Make sure that the damper rod is not bent as might happen if it has come loose from the fork capnut during operation.

7. Check the springs for damage.

ASSEMBLY AND INSTALLATION

1. Thoroughly clean all components before assembly. Give all pieces a coat of light oil.

2. Reassemble the damper tube components if this has been taken apart: crosspin cup, slotted washer. Secure the nut at the bottom of the rod, then fit the assembly into the damper tube and secure the damper cap nut.

For Scramblers, the plunger sleeve (oil groove closest to the bottom of the rod), circlip, crosspin, damper valve, valve seat, and rod nut are fitted in that order.

3. Replace the fiber washer on the lower end of the damper tube and insert the tube into the fork slider; secure it there with the bolt and washer at the very bottom of the slider.

4. Fit the bottom (steel) bush and secure it with the circlip. Be sure the circlip is not deformed. Fit a new one if in doubt.

5. From the top of the fork tube, slide on the flanged bush, the paper washer, and the oil seal. Be very careful when sliding the oil seal along the fork tube. It is advisable to apply some oil to the seal lip before refitting. Also, note that the seal is installed with the spring side (open side) facing the flanged bush.

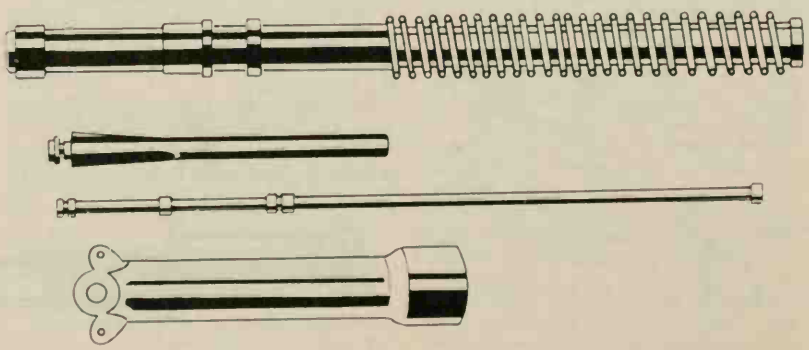
6. Take up the damper rod and fork slider, which have been assembled as directed above, and slip the internal fork spring over the damper rod. Also, fit the spacer and the nut. Be sure that the bevelled side of the nut faces the spring. Screw the nut all the way down to the end of the threads of the damper rod.

7. Take up the slider and damper assembly and insert the spring into the bottom of the fork tube. Carefully bring the fork slider up over the lower and upper bushes.

8. Place the extension into position from the upper end of the fork tube and use it to centralize and press the oil seal into the fork slider. Hand-tighten the extension. Final tightening is best left until the axle has been replaced, as this will keep the slider from turning as the extension is turned.

9. Replace the external spring (if fitted) and the fork gaiter or dust cover.

10. Lightly grease the upper portion of the fork tube and position it in the triple clamps. The clamp nut on the lower triple clamp may be gently tightened to hold the fork leg in place, if necessary.



11. Refill the fork leg with the correct grade and quantity of oil.

12. Push up the fork leg to expose the damper rod and replace the capnut and washer. Tighten the capnut against the locknut on the damper rod, then (loosen the clamp nut on the lower triple clamp if this has been tightened) tighten the fork capnut all the way to pull the fork tube up into its proper position. Retighten the lower triple clamp nut. Replace the brake lines (hydraulic). Torque the caliper bolts to 30 ft lbs.

13. Refit the fender and wheel. Tighten the fork slider extension securely.

Steering Head

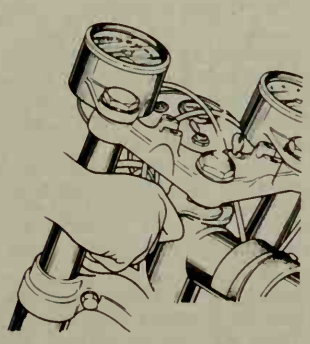
The steering head assembly should be removed to lubricate the bearings at the appropriate maintenance interval, or to inspect the condition of the bearings if

Front fork assembly (G15CS)

normal adjustment procedures do not take play out of the front forks.

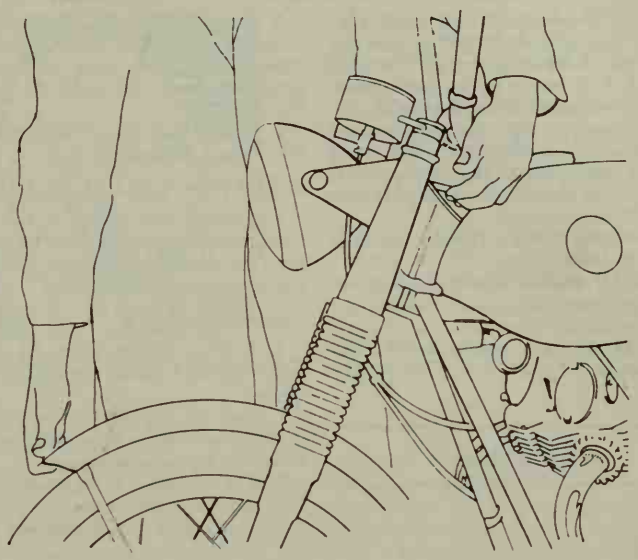
NOTE: *Latest Commando models have sealed steering head bearings installed and, therefore, the steering head is not adjustable and should not be removed except if damage is suspected as after a collison.*

EARLY MODELS



The following procedure applies to early models with adjustable steering stem bearings.

Removal



1. Remove the handlebars, the instrument drive cables, and the light wires.
2. Unbolt the headlight and let it hang from the wiring harness.
3. Remove the fork capnuts and remove the tach and speedometer.
4. Remove the front wheel and fender as previously described.
5. Remove the steering damper, if fitted.
6. Remove the fork crown nut (this is the large nut at the rear center of the upper triple clamp). Give the upper triple clamp a blow from beneath with a soft-faced mallet and remove it.
7. Support the forks and unscrew the bearing race adjuster nut; this is a sleeve nut. Watch for the 18 ball bearings in the upper race.
8. Lower the forks and remove the assembly from the frame.
9. The bearing cups in the frame are press-fit. They can be drifted out, if necessary, using a short piece of steel tubing. The cups must come out parallel to the housing, so move the tubing around the circumference of the cup while driving it out.
10. The cone on the steering column can be removed with a suitable chisel or a screwdriver.

Inspection

1. There are 36 bearings in the steering head assembly (18 in each ball race). Be sure that all are present.
2. Inspect the bearing race surfaces for ripples, cracks, rust, pitting, or signs of wear. The bearing surfaces should be smooth.
3. Make sure that the steering column is parallel with the top ends of the fork tubes.
4. Ball bearings are ¼ in. in size. They must be in good condition and free from any deformation.

Adjusting the steering head bearings (pre-1971 models)

Checking steering head bearings for excessive play

Installation and Adjustment

1. Replace the cone on the steering column and the bearing races in the frame. A draw bolt should be used to press home the races. All traces of paint or foreign matter must be removed to enable the bearings to be repositioned correctly.
2. Place 18 balls in the cone and in the top cup on the frame, holding them in place by embedding them in stiff grease.
3. Replace the dust cover, then thread on the bearing race adjuster nut (sleeve nut). This must be adjusted later. Make it reasonably tight for now.
4. Replace the upper triple clamp and seat it properly. Replace the fork crown nut, but do not tighten it.
5. Replace the front fender and wheel assembly.
6. Check the play in the front forks by grasping the tip of the front fender, pulling forward, and feeling for play with the other hand placed at the junction of the upper triple clamp and the frame.
7. To adjust the bearings, loosen the clamp nuts on the lower triple clamp (be sure that the fork crown nut is also loose), and tighten the sleeve nut with the appropriate wrench until all play in the forks is taken up.
8. Retighten the clamp nuts and the crown nut. Recheck the forks for play and also see that they can be rotated from lock to lock with no binding or tight spots.
9. The remainder of the procedure is the reverse of the removal instructions.

LATE MODELS

Late models feature two sealed ball bearings which do not need lubrication or adjustment. This type is easily identifiable since it has a large nut under the lower triple clamp.

Removal

1. Remove the front forks.
2. Bend back the locktab and remove the large nut under the lower triple clamp. Remove the triple clamp, tapping down with a plastic mallet while supporting the headlight brackets.
3. Tap the steering stem upward through the bearings to remove the stem and upper triple clamp.
4. The bearings are a press fit in the frame and are separated by a spacer tube. To remove them, move the tube to one side and drift out one of the bearings. Remove the tube and repeat the procedure for the remaining bearing.

Installation

1. Installation is the reverse of the removal procedure.
2. When the triple clamps are installed, do not fully tighten the stem nut. Install the forks, then tighten the fork top bolts, stem nut, and lower triple clamp bolts in that order. Stem nut torque is 15 ft lbs.

Rear Shock Absorbers

The rear shock absorbers are sealed units and the hydraulic damper cannot be serviced. They are adjustable for load and this change is made with the appropriate "C" wrench. The adjuster preloads the spring and turning the adjuster in a clockwise direction provides a stiffer ride when needed (as when carrying two people). Of course, both units must have the same adjustment.

The springs can be removed by:

1. Removing the shocks (one at a time) from the frame.
2. Compressing the spring sufficiently to take out the two keepers at the top.
3. Removing the dust cover (if fitted), and taking off the spring.

NOTE: *Grating noises while in operation are usually eliminated by greasing the inside of the dust cover before installation.*

The rear shocks must have some play on their mountings. It should be possible to twist the shocks slightly to either side and have them return to the center position when released. If the shocks are unable to move in this manner, remove them and check the steel mounting sleeves in the eyelets. The sleeves must protrude from the eyelet slightly. If they do not, fit new sleeves.

When fitting shocks, tighten securing bolts to 28 ft lbs.

On Mk III models, check that the bottom of the right shock clears the caliper mounting plate. Clearance can be increased by fitting a spacer behind the shock mount.

Swing Arm

ATLAS

Removal

1. Remove the chainguard. Disconnect the final drive chain.
2. Remove the rear wheel and the brake assembly.
3. Remove the bolts which attach the bottom of the shock absorbers to the frame.
4. Remove the nut and washer from one end of the swing arm spindle and take out the spindle from the other side of the frame.
5. Push the swing arm forward, turn it to one side, and take it out of the frame.

Disassembly

There are two bushes, separated by a spacer. The bushes must be removed and installed with a press.

Assembly and Installation

1. Press in the new bushes.
2. Replace the swing arm in the frame.
3. Replace and tighten the shock absorber bottom bolts before tightening the swing arm spindle nut.
4. Tighten the swing arm spindle nut and proceed with assembly in the reverse of the removal sequence.

G15CS, N15CS

These scrambler models incorporate two oilite bearings in a steel sleeve.

Removal

1. Remove the chainguard, disconnect the chain, and unbolt the rear shocks from the swing arm.
2. Remove the rear wheel and the brake assembly.
3. Take out the cotter pin on the swing arm spindle and press out the steel sleeve. Remove the swing arm. Watch for the two felt washers as the swing arm is removed.

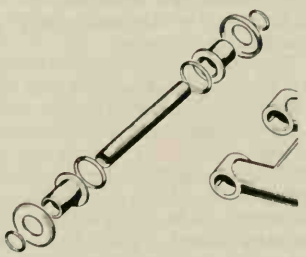
Disassembly

Each bush must be pressed out in turn with a press. Note that they are flanged.

Assembly and Installation

1. The spindle diameter is 0.990–0.995 in. The bushes are reamed, after installation, to 1.001 in.
2. The steel sleeve is oil filled and this is accomplished by removing the filler screw in the cover plate and injecting a heavy grade of oil until the cavity is filled.
3. The remainder of the procedure is the reverse of removal.

COMMANDO (1974 AND EARLIER)



The swing arm pivots on two flanged bushes which are supported by the swing arm spindle which passes through the rear engine mounting plate.

Removal

1. Remove the threaded rod which secures the end plates for the swing arm bushes.
2. Remove the lockbolt, in the middle of the rear engine mounting, which secures the swing arm spindle.
3. The spindle is threaded on the right-side. It must be removed with a ½ in. bolt. Thread in the bolt and pull out the spindle.
4. Remove the chainguard. Disconnect the drive chain.
5. Remove the rear wheel and the brake assembly.
6. Remove the bottom bolts on the rear shock absorbers.
7. The swing arm can now be removed from the frame.

Disassembly

1. Remove the large O-rings and dust covers from the swing arm.
2. Take out the small O-rings in the recesses of the bushing housings, then support the ends of the swing arm properly and press out the bushes with an arbor press.

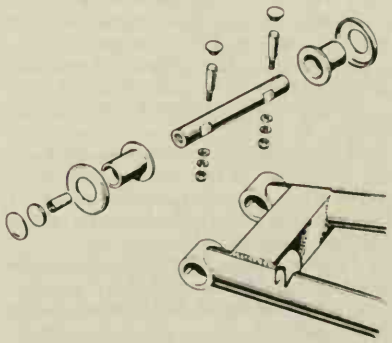
Commando swing arm bushings (to 1974)

Inspection

In the event of a damaged or worn swing arm pivot spindle, oversized units are available. These are 0.005 in. larger in diameter than the stock unit. The spindle bore clearance should be 0.0005–0.0020 in.

To fit the oversized spindle, the bearings should be bored, in place, to 0.8807–0.8817 in.

Assembly and Installation



1. Place the dust cover over the bush. The recess in the dust cover for the large O-ring should face inward.
2. Press in the bushes. Again, an arbor press is used.
3. Refit the large O-rings in the dust covers and the small O-rings in the recess in the bush housing.
4. The rest of the procedure is the reverse of that for removal.

COMMANDO (1975 AND LATER)

Removal

NOTE: *New swing arm welch plugs and felt pieces are required if the swing arm is removed.*

1. Loosen the right-side shock absorber and pull out as far as the circlips allow.
2. Hang the brake caliper from the hook provided. Remove the rear wheel.
3. Remove the right rear support plate complete with brake, pedal, and footpeg.
4. Pry out the right-side swing arm pivot welch plug. Remove the felt washers.

Commando swing arm bushings (1975 and later)

5. Remove the lower rear fender brackets. Remove the oil filter and lines. Remove the horn.
6. Remove the swing arm pivot pins by removing the nuts and driving up from the bottom. Note the rubber plugs.
7. Remove the shock absorber bottom bolts.
8. Remove the swing arm spindle. To do this, screw a bolt with a locknut into the spindle (the main front mounting bolt will work), and pull out the spindle. Disconnect the speedometer cable. Remove the swing arm.

Inspection

1. Check the spindle for wear or scoring. Inspect the bushes for signs of wear.
2. Insert the spindle into place and check for play. There should be none. If play exists, the spindle and the bushes should be replaced.

Disassembly and Assembly

1. Remove the left welch plug.
2. Press out the old bushings.
3. To install new bushes, place the sealing washer over the bush and press it in fully. The bushes do not need to be reamed after installation.
4. Place the felt disc into the recess of the left-side boss after soaking it in SAE 140 oil. Install the welch plug.

Installation

1. Soak the swing arm spindle lubricating wicks in SAE 140 oil and then install one into the left end of the spindle.
2. Place the swing arm into position with the bushes installed and the left-side felt washer and welch plug in place.

3. Carefully push in the spindle, noting the two cutouts which align with the cotter pins. When the spindle is inserted about half-way, install the left-side cotter pin. Then continue pushing in the spindle until the cotter pin mates with the cutout in the spindle.
4. Install the right-hand cotter pin.
5. Remove the bolt used to install the spindle. Install the oil-soaked felt wick into the right-side of the spindle, then the oil-soaked felt washer, and install the welch plug.
6. The remainder of the procedure is the reverse of disassembly.

Checking clearance in the front engine mounting (1974 and earlier)

5. To remove the rear engine mounting, the engine, transmission, oil tank, and the swing arm spindle must be removed.
6. The main mounting bush and the rubber spacers are removed with an arbor press. This is also true for the front assembly, although this unit may be taken out of the frame by itself.

NOTE: *If proper side-play cannot be obtained, the engine mounting tube may be partially collapsed and must be replaced.*

For other engine mounting problems, refer to the following chart:

Vibration Range	*Probable Cause*	*Solution*
0–3000 rpm	Front Mounting OK, Rear Tight	Remove 0.005 in. shim
3000–5000 rpm	Rear Mounting OK, Front Tight	Remove 0.005 in. shim
0–5000 rpm	Front and Rear Mountings Tight	Remove 0.005 in. shim

Frame

PRE-COMMANDO

The rigid frame Nortons require no maintenance in this area other than routine checks of the frame gussets and steering lug for cracks if vibration is high or handling poor.

COMMANDO

The engine and transmission are bolted rigidly together by the rear engine mounting plate. The swing arm, instead of being attached to the frame, is bolted to this assembly, although it pivots independently in the normal manner. Now, the entire engine-transmission-swing arm unit is mounted in the frame at three places by means of polymer filled absorption units. These are located at the very top of the cylinder head, at the front of the crankcase, and above and to the rear of the transmission.

The absorption units must be assembled properly if the system is to work as the designers intended.

The front and rear engine mounting units must be checked for side-play if vibration occurs.

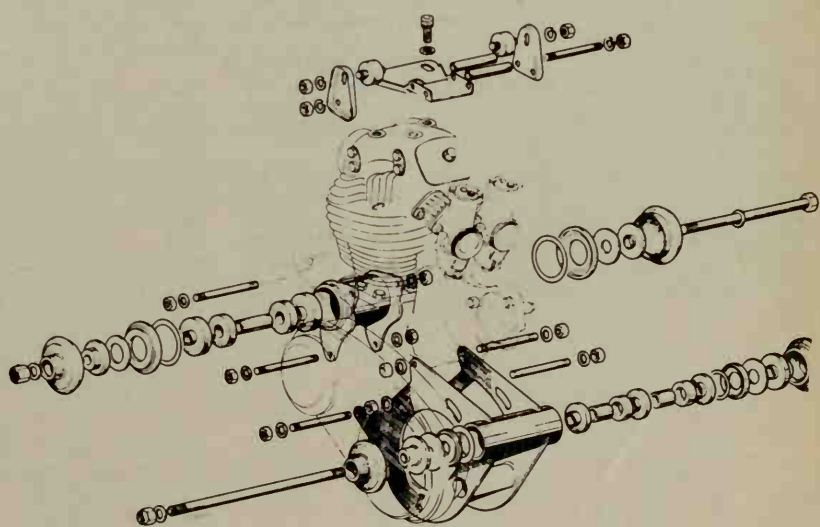
NOTE: *When checking the mountings, 1970 and earlier models may be supported on the center stand. 1971 and later models, however, must be supported with a crate or box on which the lower frame rails can rest. These models cannot be checked while on the stand, since this will put tension on the mountings.*

1974 and Earlier

Front Mounting

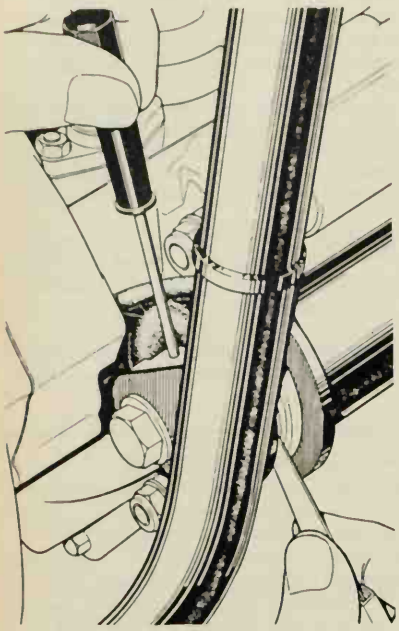
1. For the front engine mounting, be sure that the engine mounting bolt is torqued to the correct value of 25 ft lbs.
2. The total side-play of the front engine mounting should be 0.020–0.025 in. If the side play is reduced, the mounting bush will not function. Side-play is adjusted by means of shim washers of varying thickness. These are available in four sizes: 0.005, 0.010, 0.020, and 0.030 in.
3. If the engine plate is moved and then released, the assembly should react through the elasticity of the mounting bush. If it does not, the shim washers are too thick.
4. To fit new shims, remove the nut on the left side of the assembly, drive out the bolt far enough so that the spacer and the cap can be removed for access to the shim washer, and replace this with one which will give the correct side-play.
5. Reassemble the mounting, torque down the nut to 25 ft lbs, and recheck the side-play.

Rear Mounting



1. Checking the side-play for the rear mount is the same as for the front. The value is 0.010–0.015 in. It should be checked on the right-side of the machine.
2. New shims can be fitted by taking off the nut on the right-side and driving out the bolt far enough so that the spacer and cap can be removed.
3. Replace the shim washer with the one selected and refit the cap and spacer.
4. Torque down the nut (25 ft lbs) and recheck side-play.

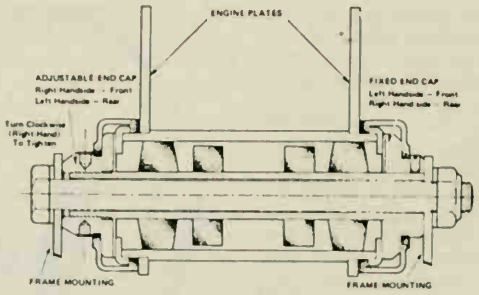
1975 and Later



The Isolastic mounts on the Mk III are similar to those found on earlier models, although they incorporate an adjusting device.

Front Mounting

1. Slide the right-side gaiter back to give access to the adjuster and plastic washer.
2. Push the engine as far as possible to the right to take up all the slack in the mounting. Hold the engine in this position and check the clearance between the plastic washer and the plated adjuster collar. If the clearance exceeds 0.010 in. (0.25 mm), adjustment will be necessary.
3. Loosen the mounting main bolt and slide the spring clip clear of the holes in the adjuster. Use a thin screwdriver or a suitable substitute and turn the adjuster until there is no clearance. Then back off the adjuster 1½ holes.



Isolastic mountings (1974 and earlier)

Adjusting clearance (1975 and later)

4. Tighten the main bolt to 30 ft lbs. Clearance should be about 0.006 in. (0.152 mm).

Mounting unit (1975 and later)

Rear Mounting

1. Slide the left-side gaiter back to expose the face ring and plastic washer.

2. Push the rear wheel as far as possible to the left and check the clearance between the plastic washer and the plated adjusting collar. If clearance exceeds 0.010 in. (0.25 mm), the mounting should be adjusted.

3. Loosen the mounting main bolt. Insert a small screwdriver or something similar into the adjuster and turn it until there is no clearance. Then back it off 1½ holes. Tighten the bolt to 30 ft lbs. Clearance should be about 0.006 in. (0.152 mm).

Maintenance

NOTE: *Common maintenance procedures are explained in detail in "General Information."*

Lubrication

ENGINE

The crankshaft bearings, cylinder and piston are lubricated by the Yamaha "Autolube" oil injection system.

The system does not require maintenance except for a periodic check on oil pump cable adjustment and stroke provided that the Autolube tank is kept full of oil. A level glass is provided for this purpose.

"Yamalube" oil is recommended by the factory. If this is not available, one of the following types of oil can also be used:

a. Any high-quality two-stroke oil labeled "BIA certified for service TC-W";

b. Any high-quality SAE 30W two-stroke oil designed for air cooled engines.

If the Autolube tank ever runs out of oil, if the feed line is disconnected for any reason, or if removal and cleaning of the tank is ever necessary due to the presence of water or other contaminants, it is necessary to bleed the system before operating the motorcycle. Refer to the "Lubrication System" section for procedures.

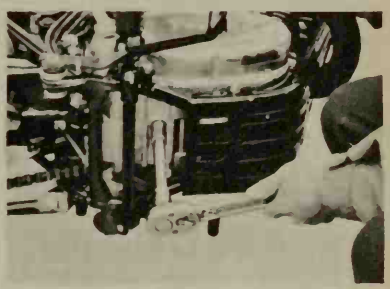
TRANSMISSION

The transmission and clutch are lubricated by an oil bath. Yamalube 4-cycle, SAE 20W/40 or SAE 10W/30 service rating "SE" is recommended for all models.

Checking Oil

1. The machine should be on the center stand or vertically supported, preferably on a level surface when checking the transmission oil level.
2. The engine should be warm.



When checking transmission oil level, the dipstick should be allowed to rest on the top of the hole (Courtesy Yamaha Int. Corp.)

3. A dipstick is provided; unscrew it and wipe it off. Reinsert, allowing the dipstick cap to rest on top of the threads of its hole. The oil level should be between the maximum and minimum marks on the dipstick. If too low, add oil until the level is correct.

Changing Oil

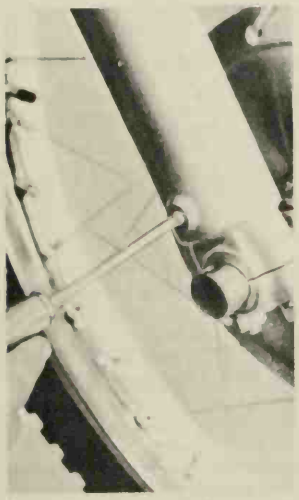
The transmission oil should be changed at least every 2,000 miles (except for competition use) after break-in is over.

1. Oil should be changed when the engine is at or close to operating temperature.
2. The machine should be supported vertically or be on the center stand and parked on a level surface.
3. Remove the dipstick.
4. Remove the drain plug and allow the oil to drain off for several moments.

Removing the transmission drain plug (Courtesy Yamaha Int. Corp.)

5. Check the condition of the drain plug gasket. Replace it with a new one if it is damaged or cracked. Refit the drain plug and tighten firmly. Torque to 30 ft lbs.
6. Fill the transmission with the cor-

rect type and quantity of oil. Capacity is stamped on the crankcase. After filling, allow a moment for the oil to distribute itself, then check the level with the dipstick or level plug.



NOTE: *The use of oil additives is not recommended since these may cause clutch slippage.*

FRONT FORKS

1. Change the front fork oil at the proper service intervals or when changing the fork's damping qualities is required. Refer to the charts at the end of this section for the fork capacity and recommended service intervals.

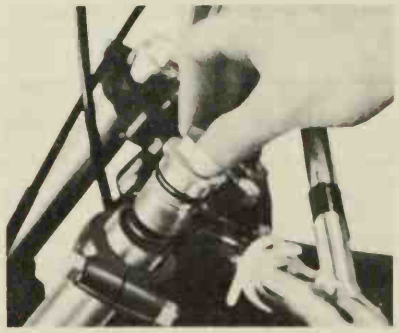
2. Yamaha fork oil or SAE 10W-30 oil is recommended for the front forks.

3. To drain the fork oil, remove the drain plug at the lower portion of one of the fork sliders. Allow the oil to drain into a suitable container; pump the slider up and down several times.

Front fork drain screw removal (Courtesy Yamaha Int. Corp.)

After most of the oil is expelled, turn the forks all the way to the right to completely drain the right fork leg, or to the left for the left fork leg. Check the condition of the drain plug gasket. Replace it if necessary. Refit and tighten the drain plug.

4. Repeat the procedure with the other fork leg.



5. Support the front wheel off the ground. Remove the fork filler bolt from the top of each fork leg. If upper triple clamp pinch-bolts are fitted, loosening these first may make removal of the filler bolts easier. On some machines, it will be necessary to loosen the handlebar clamps and move the bars to gain access to the filler bolts.

6. Add the correct quantity of oil to each fork leg.

7. Inspect the condition of the fork filler bolt O-rings if they are fitted to your model, and replace them if torn or cracked. Fit the bolts and tighten them securely. Tighten the handlebar and pinch-bolts if they were loosened.

THERMAL FLOW SHOCK ABSORBER

Unless you are using your machine in competition, there isn't any set interval for changing the oil in the thermal flow type shocks. The sealed type shocks, which don't have an external reservoir, have no provision for oil changes.

Removing the fork filler bolt (Courtesy Yamaha Int. Corp.)

Change the fluid every fourth meet if you're racing, whenever the shocks feel too spongy, if they leak, or if you'd like heavier oil to compensate for your weight or riding style.

Yamaha recommends using a high-quality 10W/30 oil rated SE; however ATF, heavier or lighter oil may be used at your discretion.

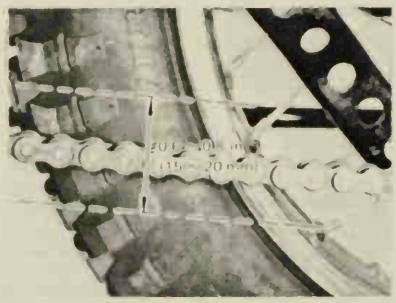
Removing the thermal-flow shock absorber oil reservoir cap (Courtesy Yamaha Int. Corp.)

To change the oil, remove the shock from the bike, then remove the rebound springs and the reservoir cap. Empty out the old oil and thoroughly flush out the entire unit. Pumping the shock will assure the expulsion of all the oil and solvent. Pour in the fresh oil while slowly pumping the shock to evenly distribute the oil, then reassemble the unit. Capacity is 6.1 oz (181 cc). Torque the reservoir cap to 14.5–16.7 ft lbs.

CHASSIS LUBRICATION

1. On most machines, the swing arm pivot is fitted with a grease nipple. This item should be lubricated with a good grade of chassis grease every 2,000 miles. Grease should be applied until some of it shows at either end of the swing arm.

2. Wheel and steering head bearings are lubricated with bearing grease. This should be accomplished every 4,000 miles. Refer to the "Chassis" section for procedures.



Service Checks and Adjustments

DRIVE CHAIN

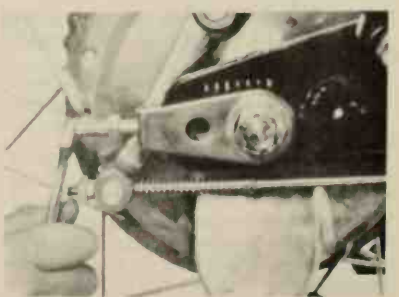
1. The chain should have about 0.6–0.8 in. (15–20 mm) of total up-and-down free-play measured in the middle of the lower chain run.

2. *Before* checking or adjusting the chain slack, the following conditions should be met:

a. The machine should be off the center stand, and with a rider sitting on the seat;

Drive chain slack adjustment (Courtesy Yamaha Int. Corp.)

b. The chain should be clean and well lubricated;



c. The chain should have been checked for any tight spots by slowly rotating the wheel and checking for variances in the chain tension at different points. If a tight spot exists, the chain should be adjusted to the prescribed free-play at the tight spot. Note, however, that such a condition is indicative of a worn chain and probably sprockets which should be replaced as soon as possible.

3. To adjust the chain, first back off the rear brake adjuster nut.

4. Remove the axle nut cotter pin and loosen the axle nut several turns. Loosen the sprocket hub securing nut (if fitted). Loosen the locknut on each adjuster bolt.

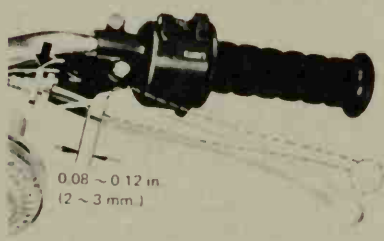
5. Turn each of the adjuster bolts (or nuts on some machines) in by equal amounts until chain tension is approximately correct.

6. Check wheel alignment by means of the adjusting marks inscribed on both sides of the swing arm. Be sure that both adjusters are lined up with the same mark

Adjusting the drive chain (Courtesy Yamaha Int. Corp.)

on each side. If not, turn one of the adjuster bolts or nuts in or out so that alignment is achieved.

7. Tighten the sprocket nut (if fitted) and the axle nut and check the chain tension. Correct if necessary. After adjustment is correct, torque the axle nut to the torque given in the Specifications chart at the end of the "Chassis" section. Fit a new cotter pin. Tighten the adjuster locknuts. Readjust the rear brake.



CLUTCH

There are two clutch adjustments: the clutch *plates* and the clutch *cable*. The clutch plates are adjusted by means of an adjuster screw and locknut located on the engine itself. This adjustment is made to compensate for wear of the plates.

The second adjustment, that of the clutch cable, is accomplished by means of the cable adjusters on the engine or the handlebar. This adjustment is made to compensate for cable stretch.

NOTE: *The clutch cable free-play must always be checked after adjusting the clutch plates.*

1. The clutch lever on the handlebar should be able to be moved 2–3 mm (0.08–0.12 in.) away from the lever holder before the clutch begins to disengage.

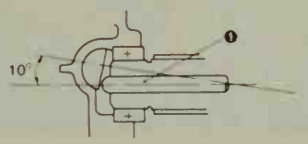
Adjust the clutch cable so that the clutch lever has the indicated amount of free-play before disengagement begins (Courtesy Yamaha Int. Corp.)

2. If adjustment is necessary, use the cable adjuster either at the handlebar or the engine until cable adjustment is correct.

3. If adjusting the cable does not provide satisfactory clutch performance, the clutch plates should be adjusted.

4. On models which have an external clutch lever on the crankcase, check the position of the clutch lever relative to the clutch pushrod. The lever should be 10° behind the clutch pushrod centerline when the clutch is engaged, and 10° in front of the pushrod centerline when the clutch is disengaged.

If the clutch crankcase lever is not properly positioned, remove the left rear (countershaft) crankcase cover to gain access to the clutch adjuster screw.



Loosen the adjuster screw locknut and tighten the screw fully. Use the cable adjuster(s) to properly position the lever just behind the pushrod centerline.

Back the adjuster screw out until the lever shaft contacts the pushrod. Then turn it in ⅛ turn and tighten the locknut.

Adjust the cable to give the proper free-play at the handlebar lever as described above.

Pull the clutch hand lever in until it contacts the hand-grip. Measure the distance from the cable holder on the engine to the center on the clutch lever clevis pin. It should be at least 55 mm (2.2 in.). If the distance is too small, use the cable adjuster to increase the distance to at least this much.

Those familiar with general clutch adjustment procedures will realize that the lifter mechanism for this type of clutch is somewhat different. The adjuster screw moves the clutch (crankcase) lever up and down. The lower end of the lever shaft is tapered, and turning the adjuster screw out will eventually bring the end of the shaft into contact with the pushrod. A slight free-play from this position is desired, which is why the adjuster screw must be turned in ⅛ turn after contact with the pushrod.

Clutch (engine) lever adjustment should be 10° behind the pushrod centerline (1) when the clutch is properly adjusted (Courtesy Yamaha Int. Corp.)

5. On other models (those which do not have a visible clutch lever on the engine), remove the clutch adjuster screw cover plate from the crankcase cover. On some models, such as the LT, AT, and CT-series, it is necessary to remove the left front crankcase cover to gain access to the adjusting screw. On the L5T, remove the carburetor cover.

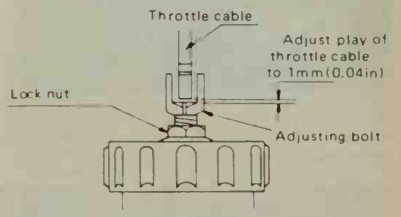
6. Turn in the clutch cable adjusters so that there is plenty of free-play in the cable.

7. Loosen the adjusting screw locknut and back the adjusting screw off a few turns. Then turn it clockwise carefully until a slight resistance is felt. Back the screw off ¼ turn, and tighten the locknut.

8. Adjust the clutch cable to the prescribed free-play, and check clutch operation.

THROTTLE CABLES

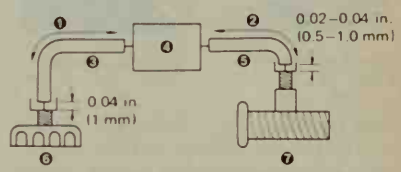
1. Throttle cables should be adjusted *after* the idle speed. This procedure is given in the "Tune-Up" section.



2. The oil pump cable must be adjusted after adjusting the throttle cables.

3. A cable adjuster is fitted to the top of the carburetor and another at the twist-grip. One throttle cable runs from the twist-grip to a junction box. There, it is connected to the oil pump cable and a shorter throttle cable which runs to the carburetor. Therefore, each cable must be adjusted.

Clutch adjusting screw and locknut (Courtesy Yamaha Int. Corp.)



4. After setting the idle speed, use the adjuster on the carburetor cap to give 1 mm (0.04 in.) of cable free-play. This can be measured by gently lifting the cable out of the adjuster. It should come out no more than the amount shown before the throttle slide begins to rise. Loosen the locknut and screw the adjuster clockwise (in) to increase the slack and counterclockwise (out) to decrease it. Tighten the locknut.

Throttle cable free-play adjustment at the carburetor cap (Courtesy Yamaha Int. Corp.)

5. Adjust the long throttle cable with the adjuster at the twist-grip. This cable should be adjusted to give 0.5–1.0 mm (0.02–0.04 in.) of free-play.

6. Adjust the oil pump cable.

2. Longer throttle cable free-play
3. Short cable

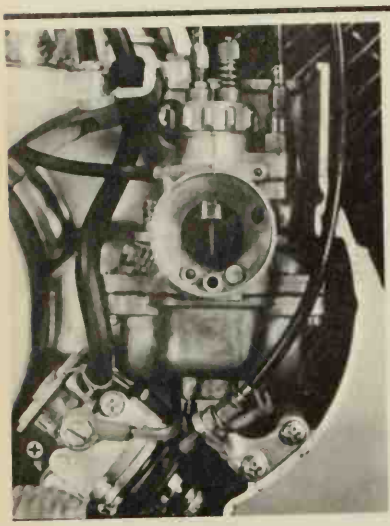
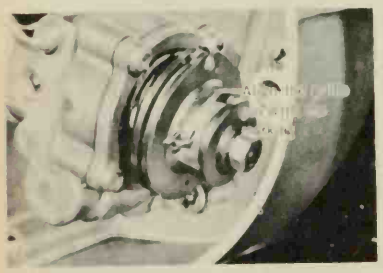
OIL PUMP CABLE



NOTE: *This procedure MUST be done after adjusting the throttle cable free-play.*

1. Set the throttle cable adjustments as described above.



2. Remove the oil pump cover. On rotary valve models, this will expose the carburetor as well.

3. On rotary valve models, note the punch mark on the throttle slide. Turn the throttle twist-grip until the upper part of the punch mark aligns with the top of the carburetor bore. Holding the throttle in this position, check that the mark on the oil pump pulley is aligned with the oil pump guide pin. If it is not, loosen the locknut, and turn the oil pump cable adjuster in or out until alignment is achieved. Tighten the locknut.

4. On piston-port models, turn the throttle twist-grip until all slack is taken out of the cables, but the throttle slide has not moved. At this point, the raised mark on the oil pump pulley should align

The oil pump cable should be adjusted when the throttle slide punch mark is aligned with the top of the carburetor bore

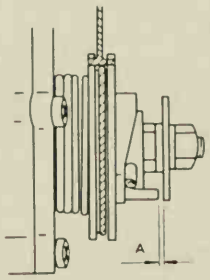
with the oil pump guide pin. If it does not, loosen the locknut on the oil pump cable adjuster located in the side cover and turn the adjuster in or out until adjustment is achieved. Tighten the locknut on the adjuster.

MINIMUM OIL PUMP STROKE

Before beginning, have a feeler gauge of the correct size at hand. The minimum oil pump strokes are as follows:

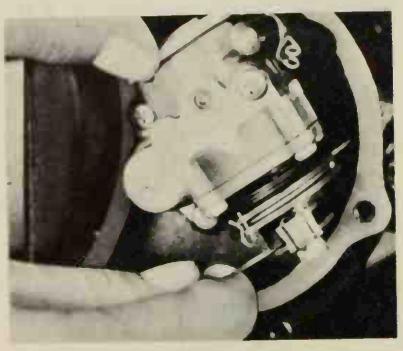
JT2L/M, GT1/MX	0.30–0.35 mm
All other models	0.20–0.25 mm

Note the following terms: the *starter plate* is the plastic disc at one side of the oil pump and is used to operate the pump by hand. The *adjustment pulley* is that to which the oil pump cable is attached. The *adjustment plate* is the small plate at the opposite end of the pump from the starter plate. It is secured by a locknut.



1. Remove the oil pump cover. Make sure that the throttle twist-grip is fully closed.

2. Slowly turn the starter plate by hand in the direction of rotation indicated by the arrow on the plate. As the starter plate is turned, a gap will be created between the adjusting plate and the pulley. Continue to turn the starter plate until this gap is at its maximum width. This can be done by gauging the gap with your eye.



3. Insert the correct sized feeler gauge between the adjusting pulley and the adjusting plate. The clearance between the two should be within the specification given.

Removing the adjusting plate locknut (Courtesy Yamaha Int. Corp.)

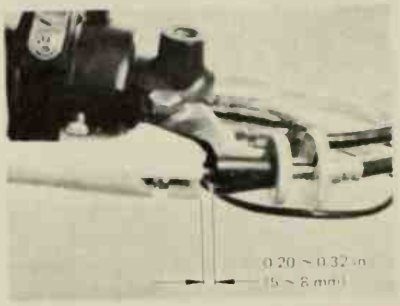
Minimum oil pump stroke (A) (Courtesy Yamaha Int. Corp.)

Minimum oil pump stroke adjustment: check the gap between the plate and the pulley (Courtesy Yamaha Int. Corp.)

4. If the clearance is not correct, remove the adjusting plate locknut, then the adjusting plate. Add or remove the 0.1 mm adjusting shims (supplied for this purpose) to the oil pump shaft to correct the adjustment, then refit the adjusting plate and tighten the locknut securely. Recheck the clearance.

NOTE: *If the original adjusting plate-to-pulley clearance was too great, remove a shim; if it was too small, add a shim or shims.*

BRAKES



Front

The front brake can be adjusted at either the front brake hub or at the handlebar lever. Unless the cable has stretched considerably, most adjustments can be made at the hand lever.

Adjust the cable by loosening the handlebar adjuster locknut and screwing the adjuster in or out so that the brake lever will move 5–8 mm (0.2–0.3 in.) before the brake shoes contact the drum.

Add or remove adjusting shims to the oil pump shaft to correct the minimum stroke (Courtesy Yamaha Int. Corp.)

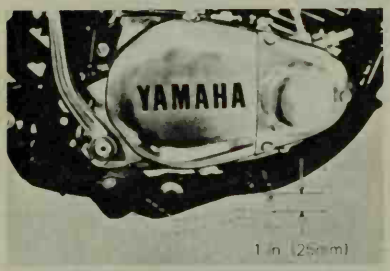
Front brake lever adjustment (Courtesy Yamaha Int Corp.)

This value is measured between the handlebar lever and the holder as illustrated.

When the handlebar adjuster comes close to the end of its adjustment range, adjust the brake using the hub adjuster as follows:

a. Turn the handlebar adjuster in so that the cable has as much free-play as possible;

b. Loosen the locknut on the hub-mounted cable adjuster, and screw the adjuster out until the adjustment is close to the proper specification. Tighten the locknut.



c. Use the lever adjuster as necessary so that the brake lever has the correct amount of movement before the brakes contact the drum.

Rear

Adjustment is made by means of the nut on the end of the brake rod. The brake pedal should move about 25 mm (1 in.) before the shoes contact the drum. This measurement should be made with the weight of the rider on the machine. Turning the adjusting nut clockwise will decrease pedal travel, rotating it counterclockwise will increase it. The adjuster nut is turned in increments of ½ turn.

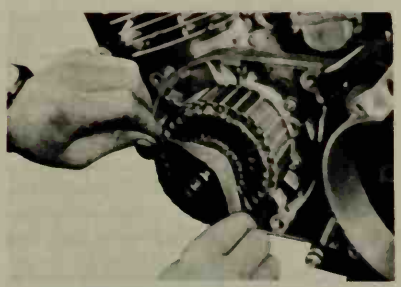
NOTE: *After adjusting the rear brake, check the brake light switch adjustment.*

If, after adjusting the brakes, the angle formed by the brake cable or rod and the lever on the brake hub is seen to be greater than 90° when the brake is applied, the lining thickness should be checked.

The rear brake pedal should have about 1 in. of free-play before the shoes contact the drum (Courtesy Yamaha Int. Corp.)

Brake Light Switch

The switches should be checked for operation after the brake is adjusted. The rear brake light switch is mounted in a slotted bracket and secured by locknuts. Moving the light switch up on the bracket allows the brake light to turn on sooner. Moving it down allows it to come on later. Generally, the brake light should come on just before the linings contact the drum.



STEERING STEM AND SWING ARM

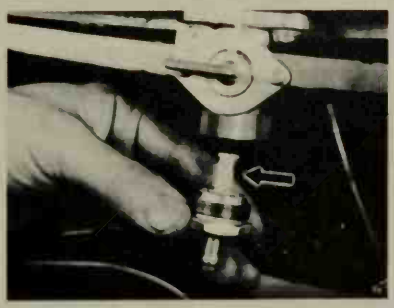
The steering stem bearing adjustment must be checked periodically, and the swing arm bushing should be checked for wear. Both procedures are given in the "Chassis" section.

GENERATOR

1. Begin inspection of the carbon brushes on machines with (DC) generators after 4,000 miles. Brushes will usually have a wear limit line marked on them. Replace them if worn to near the limit line.

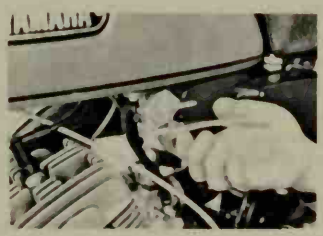
2. Clean off the generator commutator with a gasoline-soaked rag. The commutator surface can be polished with #400–600 sandpaper or fine emery cloth. After polishing, clean the commutator thoroughly.

Cleaning the generator commutator surface (Courtesy Yamaha Int. Corp.)



Fuel System

1. Fuel system maintenance involves cleaning the petcock and filter, cleaning or replacing the air cleaner, and cleaning the carburetor.



2. The carburetor should be removed, disassembled, and cleaned every 4,000 miles. The procedures are outlined in the "Fuel Systems" section.

3. The petcock should be serviced every 2,000 miles. On early models, shut the fuel off, then unscrew and remove the petcock sediment bowl. Take out the fuel filter. Clean the parts in a solvent and reinstall. Check for leaks.

Late models have no sediment bowl, but a filter screen is incorporated into the petcock. Shut the fuel off and disconnect the fuel line from the petcock. Unscrew and remove the fuel line fitting nut, which will come away with the filter screen. Clean the screen, or replace it if punctured or badly clogged.

Removing the petcock (late models) (Courtesy Yamaha Int. Corp.)

Removing the fuel petcock sediment bowl (Courtesy Yamaha Int. Corp.)

4. The air cleaner should be serviced or replaced every 1,000 miles, depending on conditions. If the air cleaner is the paper type, it should be kept free of water, solvents, etc.

The paper filters can be cleaned, after a fashion, by tapping off heavy dirt deposits, or brushing them off the outside, and blowing compressed air through the inside of the filter element. This technique, however, is limited in usefulness, and it is really preferable to replace the element every 2,000 miles or so (once again, depending on conditions).

If a foam-type air cleaner is used, wash it in gasoline to remove dirt, and squeeze until it is dry. Immerse the filter in light motor oil (20 or 30W) and squeeze off the excess oil. Then install on the machine.

Tune-Up

NOTE: *Common tune-up procedures are explained in detail in "General Information."*

Contact Breaker Points

LOCATION

1. On machines with magneto ignition, breaker points are located beneath magneto rotor on the left-side of the engine. Remove the left-side engine cover to gain access to the points. Cutouts are provided in the rotor to allow the points to be cleaned and gapped.

2. On machines with battery-and-coil ignition, the points are located beneath a cover plate on the left-side engine case.

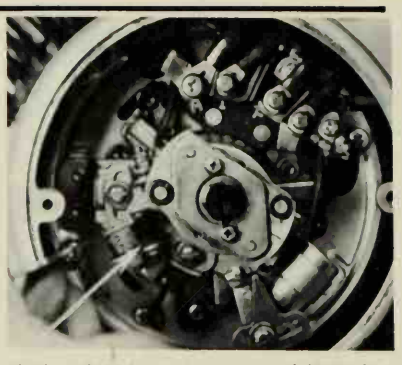
GAPPING

Points should be filed (if necessary) and cleaned before gapping.

Magneto Ignition

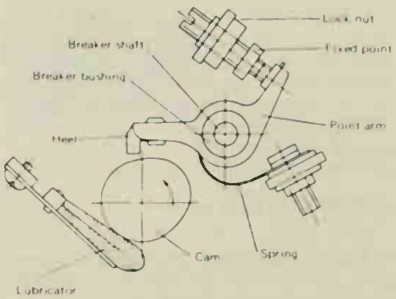
Point gapping must be accomplished in conjunction with ignition timing. Refer to that section.

Battery Ignition



1. Remove the points cover, and turn the engine over until the points are fully open.

2. With the proper feeler gauge, check the point gap. Be sure to use the correct gap for your machine as given in the "Tune-Up Specifications" chart.



3. The feeler gauge should be a light slip fit between the points.

4. If the gap is not within specification, it must be adjusted. On older models (those with a fixed point secured by a locknut), loosen the locknut and screw the fixed point in or out on its bracket so that the gap is correct. Secure the locknut.

On all newer models, the fixed point is a part of a plate and is secured with a screw. Loosen the fixed point securing screw and with a thin screwdriver applied to the pry slot provided, move the fixed point toward or away from the movable point until the gap is correct. Tighten the fixed point securing screw and recheck the gap.

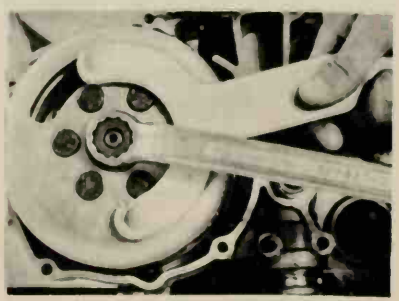
REPLACEMENT



Magneto Ignition

Two special tools are needed to replace the points on magneto-ignition machines. A rotor holder is used to hold the magneto flywheel steady while the nut is removed, and a special puller, threaded into the center of the rotor, is used to pull it off its tapered shaft.

CAUTION: *The rotor puller is essential for this job. It is not wise to attempt to remove the rotor in any other way.*

1. Remove the left-side engine cover, after loosening the pinch-bolt and pulling the gearshift lever off its shaft. The use of an impact driver to remove and install phillips head case screws is recommended.

2. Holding the magneto rotor with the

special tool, or a suitable substitute, loosen and remove the rotor nut.

3. Thread the rotor puller into the rotor. The puller bolt should be backed off enough so that the puller outer has a good number of threads in the rotor.

NOTE: *The puller outer has a left-hand thread. Thread it into the rotor in a counterclockwise direction.*

4. Tighten the puller bolt against the end of the crankshaft to remove the rotor. The rotor should come off the taper. If it is stuck, tighten the puller bolt as much as possible, and give it a sharp rap with a hammer. This should free the rotor. Note the key fitted to the crankshaft.

Removing the rotor with the special puller (Courtesy Yamaha Int. Corp.)

CAUTION: *Never use heat in an attempt to remove the rotor, since this may affect its magnetic properties. Handle the rotor with care: avoid dropping or striking it, as this, too, will affect its magnetism.*

5. Disconnect the primary wire from the breaker point terminal, then remove the securing screw. Remove the old points set.

6. Clean the contact surfaces of the new set of points to remove any protective coating present. Install the points and reconnect the primary wire.

7. Grease or oil the crankshaft taper slightly before fitting the rotor to make removal easier next time. Line up the slot in the rotor with the key in the crankshaft. Push the rotor into place. If the puller is still fitted, strike the puller bolt once or twice to ensure that the rotor is firmly seated, but do not strike the rotor itself. Refit the rotor nut and tighten it securely. Reset the point gap and check the ignition timing.

Battery Ignition

1. Remove the breaker point cover.

2. Disconnect the primary wire at the breaker points terminal, and remove the securing screw(s). Remove the old points.

3. Before installing new points, be sure to clean off the breaker point surfaces with a solvent to remove any protective coating.

4. Install the new points, tightening the securing screw(s) lightly. Reconnect the terminal primary wire. Be sure that the small nut is firmly secured.

5. Adjust the point gap, and recheck the ignition timing.

LUBRICATION

1. Whenever the point gap is checked or points replaced, it is necessary to lubricate the cam follower fiber heel and the pivot point of the contact breaker.

2. A small dab of grease (high melting point, if possible) or oil should be applied to the lubricator felt so that the lubricator can distribute it onto the breaker cam. A drop of engine oil should be applied to the pivot point.

3. In both cases it is imperative that care be taken to keep the lubricant away from the points.

4. The lubricating felt should be adjusted so that it just contacts the breaker cam.

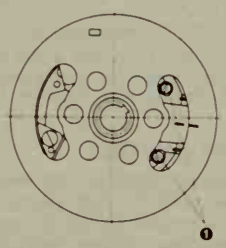
5. If the felt is missing, or the model not equipped with it, the grease can be sparingly applied to the cam itself.

Ignition Timing

CDI MODELS

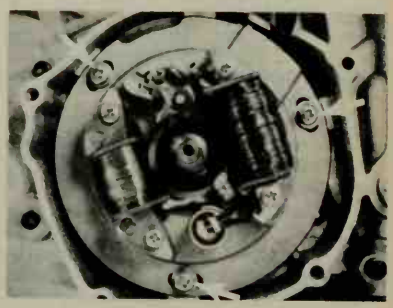
A dial indicator is necessary to set the ignition timing.

1. Remove the spark plug and insert the dial gauge into the plug hole.



2. Remove the left front crankcase cover.

3. Turning the magneto rotor slowly by hand, rotate the engine until the dial gauge needle reaches the highest reading and begins to reverse. When the needle is at the highest reading, the piston is at Top Dead Center. Turn the engine back-and-forth a few degrees in either direction until TDC is exactly determined. Position the piston at that point. Set the dial gauge to read zero.



4. Turn the magneto rotor *clockwise* until the dial gauge reads about 4 mm before TDC.

5. Rotate the flywheel slowly in the *counterclockwise* direction until the dial gauge indicates that the piston is at the firing point: proper number of millimeters before TDC as indicated in the "Tune-Up Specifications" chart. When the piston is at this position, the mark on the rotor must line up with the mark on the pulser coil.

6. If the marks do not line up, loosen the two pulser set screws and rotate the pulser until the marks line up. Tighten the screws and recheck the timing. These marks must be in exact alignment. Do not settle for an approximation.

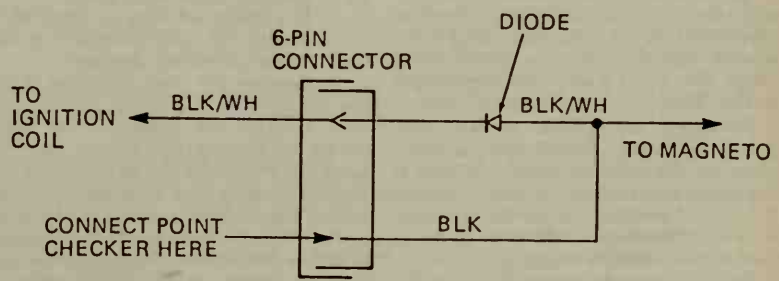
On models with slotted breaker plate holes, center the mounting scores in the slots if the plate has been removed



MAGNETO IGNITION

Some 1974 and later models have a breaker point plate with slotted holes for the three mounting screws. If the plate has been removed for any reason, center the mounting screws in these slots before setting timing.

Models such as the DT100 and DT175 have a diode in the black/white wire coming from the points. It is not possible to obtain a Points Checker reaction if the Checker is connected to this wire. Therefore, on these models, disconnect the magneto wires at the plastic connector. Note that a black wire coming from the magneto has no connection going to the ignition coil. This black wire by-passes the diode. Connect the positive lead of the Point Checker to this wire, and the negative lead to ground on the engine or frame.

Some models, such as the DT175C, have a spark advance mechanism built into the magneto flywheel. The advance mechanism must be locked into the full-advance position when checking the ignition timing.

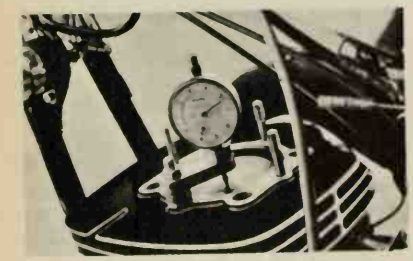
1. The ignition timing is adjusted by changing the breaker point gap. A dial gauge and a point checker are necessary

Ignition timing point checker connection for diode-equipped models (1974 and later 100–175 cc) (Courtesy Yamaha Int. Corp.)

for ignition timing.

2. Remove the magneto cover. Inspect the condition of the breaker point contact surfaces. Clean them thoroughly.

3. Turn the rotor so that the points are fully open and check the gap with a feeler gauge. The proper specifications are given in the "Tune-Up Specifications" chart at the end of this section.



4. If the gap is not within the given specification, it must be adjusted. The fixed point is secured with a screw. Loosen the screw and, with a thin screwdriver applied to the pry slot provided, move the fixed point toward or away from the movable point until the gap is correct. Tighten the fixed point securing screw and recheck the gap.

5. Remove the spark plug. On models with an angled spark plug hole, remove the cylinder head. Install the dial indicator.

6. Position the piston at top dead center by turning the engine over by hand until the dial gauge indicates the highest reading and then begins to reverse. The highest reading is top dead center. Turn the crankshaft a few degrees in either direction to check your finding, then position the piston at TDC and zero the gauge.

7. Attach the negative (black) lead of the ohmmeter or Point Checker to the engine case (ground) and the positive (red) lead to the breaker point primary wire coming from the magneto. This primary wire is colored black. On DT100 and 175, connect the Checker to the diode by-pass (black) lead at the connector.

8. Turn the engine "backward" (turn the rotor clockwise) until the dial gauge indicates that the piston is about 4 mm BTDC. Since most models fire about 2 mm BTDC, the breaker points will be fully closed at this point, as indicated by zero resistance on the meter.

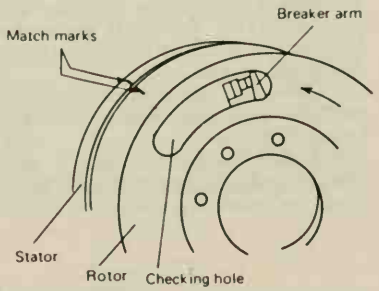
9. Slowly turn the engine in the normal direction of rotation (counterclockwise) until the dial gauge indicates that the piston is at the firing point. This point is given for each model in the "Tune-Up Specifications" chart.

10. When the piston reaches this point, the points should open as indicated by the reaction of the checker. If the points open before the piston reaches the correct position, the timing is too advanced. If they open when the piston is past it, the timing is retarded.



11. If adjustment is necessary, loosen the breaker point securing screw, and use a thin screwdriver on the pry slot provided to increase or decrease the point gap until the timing is right on. It should be possible to correct the timing while keeping the point gap within the specification given.

12. If the timing was too advanced, *decrease* the point gap. If it was too retarded, *increase* the gap.

13. Recheck the ignition timing, and repeat the procedure, if necessary until the points open at the instant the piston reaches the correct distance BTDC. Timing should be accurate to within 0.1 mm of the given value.

14. After setting the timing, recheck the point gap in the fully open position. It should still be within the proper specification. If it is not, the fiber heel on the points is probably worn and the points should be replaced.

NOTE: *Although not guaranteed to give accurate results, the timing can be set in emergency situations with the timing marks inscribed on the rotor and crankcase, if fitted to your machine. The point at which the contact breakers open can be determined with a very thin piece of paper or cellophane, if a meter is not available. Trap the paper between the closed points, and tug lightly while slowly rotating the engine. When the paper is freed, the matching marks should be lined up as shown in the illustration. Due to the inaccuracies involved in this method, it is not recommended except in emergency cases.*

BATTERY IGNITION

On battery ignition machines, a dial gauge is used to find piston position, while the moment of points opening can be determined either with the Point Checker, or with a test or continuity light.

1. Remove the points cover, and clean and gap the breaker points.

2. If a timing advance mechanism is fitted, wedge the counterweights in the OPEN (fully advanced) position.

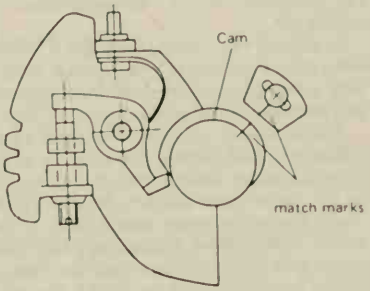
3. Remove the spark plug and fit the dial gauge.

4. Position the piston at top dead center by turning the engine over by hand until the dial gauge indicates the highest reading and then begins to reverse. The highest reading is top dead center. Turn the crankshaft a few degrees in either direction to check your finding, then position the piston at TDC and zero the gauge.

5. Refer to the "Tune-Up Specifications" chart at the end of this section for the proper timing for your machine. Ordinarily, the firing point will be 2 mm or more BTDC.

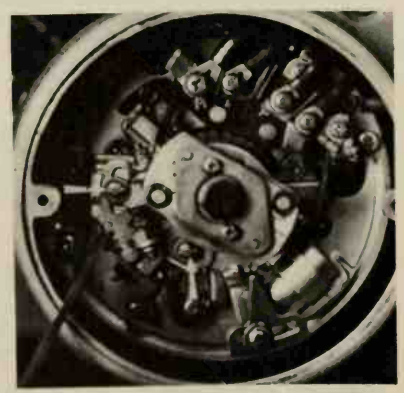
6. Hook up the test light or Point Checker: one lead to ground on the engine or frame, the other to the primary wire terminal of the points.

7. Turn the crankshaft opposite the normal direction of rotation to about 3–4 mm BTDC. The points should be closed at this position.



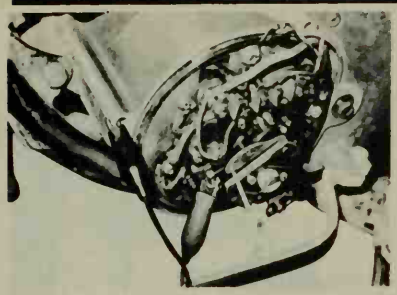
8. Slowly rotate the engine in the normal direction of rotation. When the dial indicator shows that the piston is at the proper distance BTDC, the points should open.

9. If the points open before the piston reaches this distance, the timing is too advanced; if they open after it passes the timing distance, the timing is retarded.



10. To adjust the timing, loosen the two timing screws which hold the large point mounting plate to the generator housing just enough to allow the points to be moved. Move the points in the direction of crankshaft rotation to correct advanced timing; move them opposite the direction of crankshaft rotation to correct retarded timing.

11. After adjustment, recheck the timing. The points should open at the precise instant that the dial gauge indicates that the piston is correctly positioned. Accuracy must be within 0.1 mm of the given specification.



NOTE: *Tightening the timing screws may change the timing slightly. So check your setting after they are secured.*

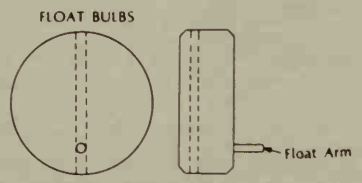
Carburetor

Three adjustments to be made to the carburetor are float level, idle mixture, and idle speed. For the first of these, the carburetor must be removed from the machine.

NOTE: *JT1 and JT2 models and bikes equipped with the early Y16P carburetor do not have an adjustable float level. If the float needle valve, part of which is attached to the bottom of the float, is in good condition and the float is not damaged or leaking, the float level is correct as set by the factory.*



ADJUSTING FLOAT LEVEL

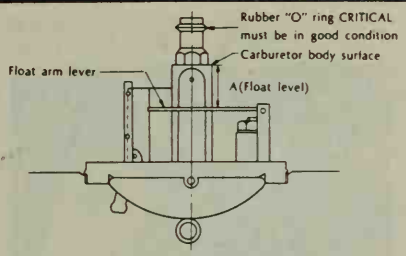
Independent Floats

As the name implies, a carburetor with independent floats has a float assembly consisting of two float bulbs and a float arm. The bulbs are not soldered to the float arm as in interconnected float carburetors.

1968–1973 Models

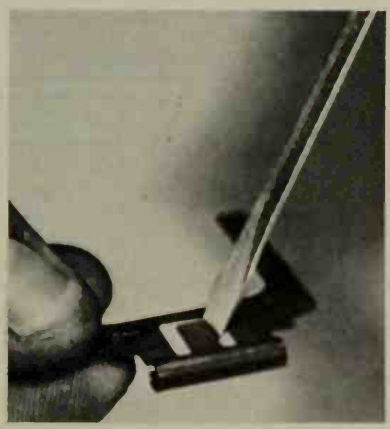
1. Remove the carburetor as outlined in the "Fuel Systems" section.

Independent floats must be installed with the float arm toward the bottom of the float bowl (Courtesy Yamaha Int. Corp.)



2. Turn the carburetor upside down and remove the float bowl screws. Lift the float bowl carefully off the carburetor body. Note that the floats will remain in the float bowl, so exercise caution while handling.

3. Make sure that the float needle and seat are clean. With the needle in place in its seat, carefully lower the float arm lever until it just touches the needle. Measure the distance from the carburetor body surface to the float arm lever as illustrated. This is the float level. Compare your finding with the correct value given in the "Tune-Up Specifications" chart at the end of this section.



NOTE: *When measuring float level, the float arm lever should just be resting on the spring-loaded needle, but not depressing the spring.*

4. If adjustment is necessary, carefully bend the float arm tang to achieve the proper float height.

NOTE: *Float level will not be correct if the float needle is worn, or if there is foreign matter on the needle or seat.*

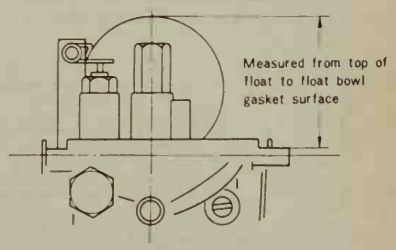
1974 and Later Models

The float level adjustment procedure is basically the same as that outlined for 1968–1973 models, above, with the exception that float level is measured from the float bowl gasket surface (gasket removed) to the float arm lever as illustrated.

Float level adjustment-independent float carburetors, 1974 and later (Courtesy Yamaha Int. Corp.)

Interconnected Float Carburetors

The float bulbs are soldered to the float arm on this type of carburetor, making a one-piece float assembly.



1. Remove the carburetor as outlined in the "Fuel Systems" section.

2. Turn the carburetor upside down, and remove the four float bowl screws carefully lifting off the float bowl.

3. Remove the float bowl gasket.

4. Float level can be measured with a steel rule or a vernier caliper. Float height is defined as the distance from the float bowl gasket surface to the top of the float, when the tang of the float arm is just touching the float needle.

NOTE: *Lower the float down until the tang just contacts the float needle. Hold the float in this position, then measure the float level.*

Float level adjustment, interconnected-float carburetors (Courtesy Yamaha Int. Corp.)

5. Compare the value obtained with the correct specification for your machine given in the "Tune-Up Specifications" chart at the end of this section. If the float level is too high or low, pull out the pin which holds the float in place, and bend the tang very slightly to correct the adjustment.

NOTE: *If float level is too high, bend the tang away from the carburetor body. If too low, bend it toward the carburetor body.*

6. Refit the float and recheck the adjustment.

CAUTION: *Bend only the float tang to make an adjustment. Do not bend the float arms. The floats must be level. If the floats show different heights, the float assembly should be replaced. This indicates that the float assembly has been mishandled.*

7. Float level will not be correct if the needle is worn, or if there is foreign matter on the needle seat.

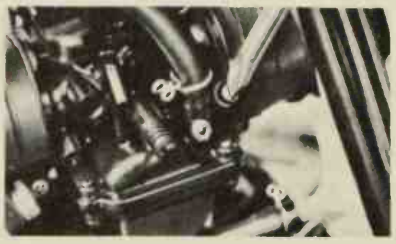
IDLE SPEED AND MIXTURE

NOTE: *These must be adjusted when the engine is at operating temperature.*

1. On all rotary valve, and the smaller piston-port models, the idle speed (or throttle stop) screw is located on the carburetor top. On other models it is located on one side of the carburetor body.

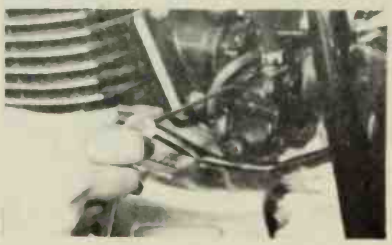
2. On some rotary valve models, the pilot air screw is located in the carburetor mouth, and is accessible after removing the carb cover plate. On all other models it is located on one side of the carburetor body.

3. The throttle cable(s) should be adjusted after making the idle speed and mixture adjustments. After adjusting the throttle cables, adjust the oil pump cable. Both of these operations are covered in the "Maintenance" section.



4. Ensure that the throttle cable adjustment is approximately correct so that the cable has enough slack to allow the throttle slide to be fully closed.

5. Screw the pilot air screw in (carefully) until it bottoms lightly, then turn it out the number of turns shown in the "Tune-Up Specifications" chart.



6. Start the engine. When operating temperature is reached, adjust the throttle stop screw (if necessary) so that the engine idles as slowly as possible. Then turn the pilot air screw in or out until the engine runs smoothly. It should not be necessary to vary the air screw more than ½ turn in either direction from the given setting.

7. Adjust the throttle stop screw so that the engine idles at the desired rpm.

8. After idle speed and mixture are set, adjust the throttle cable and oil pump cable as outlined in the "Maintenance" section.

16. Remove the engine mounting bolts and lift the engine out of the frame.

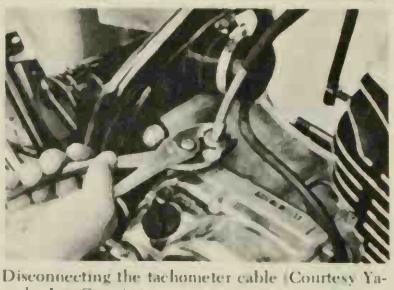
INSTALLATION

All Models

Installation is basically the reverse of the removal procedure. Note the following points:

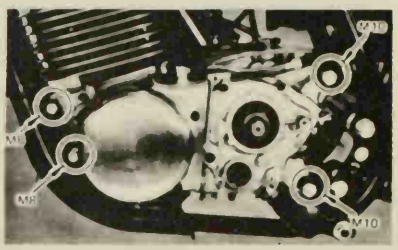
1. Engine mounting bolts should be firmly secured and checked for tightness after a run of a few miles.

2. Install the drive chain masterlink spring clip with the closed end facing the direction of chain rotation as shown.



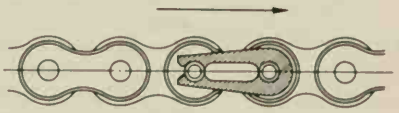
3. Replace any worn or damaged exhaust system gaskets.

4. When installing the carburetor, if it is mounted on the manifold with nuts, be sure that the O-ring is not pinched between the carburetor flange and the manifold. Tighten the two flange nuts gradually and evenly. Do not overtighten.



5. Bleed the oil pump before operation.

6. Be sure that all oil and fuel lines are secured with spring clips.



7. Check chain and cable adjustments before operation.

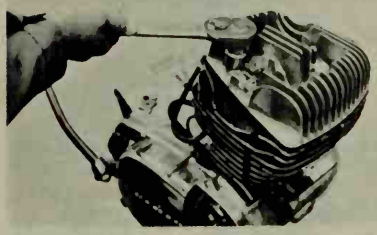
CYLINDER HEAD, CYLINDER, AND PISTON

Removal

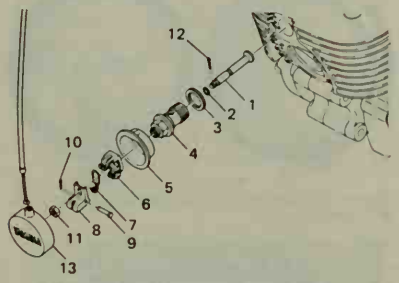
1. Clean the engine thoroughly to remove any dirt or deposits. The area around the cylinder base is especially important. Remove the gas tank if necessary.

2. Remove the spark plug.



3. Disconnect the exhaust pipe from the cylinder.

4. On piston port motorcycles, remove the carburetor from the cylinder.



5. Loosen the cylinder head nuts or bolts ¼ turn at a time in an "X" pattern until they are loose, then remove them and their washers.

6. Remove the cylinder head and the aluminum cylinder head gasket as well.

NOTE: *The cylinder head may become stuck to the cylinder due to carbon build-up. In this case, tap around the lower edge of head with a plastic mallet until the head is free. Do not strike the cooling fins.*

9. Pin

7. Remove the compression release, if necessary. On piston port models, disconnect the oil feed line banjo at the cylinder. Wrap a piece of plastic around the banjo, bolt, and washers. Secure it with a rubber band to prevent the entry of dirt. If cylinder securing nuts are fitted, loosen each one ¼ turn at a time in a cross pattern until they are loose, then remove them.

8. Place the piston at top dead center and lift the cylinder off the crankcases until there is enough room to stuff a clean rag between the cylinder and the cases. Pull the cylinder straight up, catching the piston with one hand when the cylinder is free so that the piston won't hit the studs.

NOTE: *If the cylinder is stuck, it may be freed by tapping around the fins with a plastic mallet.*

9. Remove and discard the cylinder base gasket. Remove all traces of old gasket from the crankcase and cylinder mating surfaces.

10. Remove the piston wrist pin snaprings with needlenose pliers. Grasp the piston with one hand and push out the wrist pin with a suitable drift. If the pin will not come out, the piston crown may be heated, evenly and gently, with a propane torch. If the pin still resists, it is advisable to use the shop wrist pin removal tool. This consists of a steel band or bands which fit around the piston while the attached screw device is used to push out the pin.

Removing the cylinder nuts (Courtesy Yamaha Int. Corp.)

Removing a wrist pin snap-ring (Courtesy Yamaha Int. Corp.)

11. When the wrist pin is about ¾ in. out of the piston, grasp the exposed end and pull it out until it is clear of the connecting rod. Remove the piston from the engine.

12. Most models are equipped with a caged needle small end bearing which is a slip fit in the connecting rod. The bearing may be removed to prevent loss.

CYLINDER HEAD

Inspection

1. Maximum allowable cylinder head warpage is 0.13–0.15 mm (0.005–0.006 in.).

CYLINDER AND PISTON

Inspection

1. If the cylinder walls are scratched, hone them and check for condition afterwards.

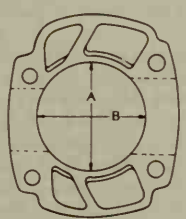
If scratches or score marks deeper than 0.03–0.05 mm (0.001–0.002 in.) remain, the cylinder should be bored out to the next oversize.

2. To check for wear of the bore, use an inside micrometer and take bore diameter measurements at the following points, holding the instrument in line with the intake and exhaust ports: just below the top edge of the cylinder; just above the exhaust port; just below the lower edge of the exhaust port; just above the top edge of the cylinder spigot. Record the diameters. Then turn the micrometer 90° and take another set of readings at the same points.

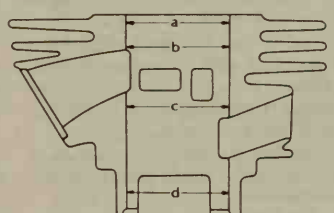
3. If the difference between the highest and lowest of these eight measurements exceeds 0.05 mm (0.0019 in.), or the difference between any two taken at the same level exceeds 0.01 mm (0.00039 in.), the cylinder should be bored and the next oversize piston fitted (see below).

4. With a micrometer, measure the diameter of the piston perpendicular to the wrist pin at a point 10 mm above the bottom edge of the piston skirt. Compare this reading of the piston diameter with the *smallest* of the cylinder bore measurements made earlier. Subtracting the piston diameter from the smallest of the bore measurements will give the piston-to-cylinder clearance. If the measured value is more than 0.1 mm (0.0039 in.), the cylinder should be bored and the next oversize piston fitted.

If the wear has occured primarily on the piston, fitting a new piston of the same original size you have might serve to bring the clearance into tolerance. This is, however, not often the case.



5. If the cylinder must be bored, first obtain the correct oversize piston and rings. Oversize pistons are available in two to four oversizes depending on model. Sizes range from 0.5 mm (0.02 in.) to 1.5 mm (0.060 in.).



Measure the diameter of the new piston, add the correct clearance for your model given in the "Piston and Ring Specifications" chart at the end of this section, and have the piston bored to the sum of the two.

After the cylinder is bored, use a small file to put a slight chamfer on the edges of all the ports. This is important since rings will catch on the edges of unchamfered ports.

Be certain that the bore is cleaned thoroughly, and that all foreign matter in the area is removed. Coat the bore with two-stroke oil.

6. There are several types of rings

Measure the cylinder bore at the four positions shown on the right and in the directions "A" and "B" (Courtesy Yamaha Int. Corp.)

having different shaped cross-sections. One type, the "plain" type ring, has a nearly square cross-section. The other two types are the "Keystone" or wedge-shaped, and the "L" shaped rings. These latter types are usually used as the top ring, although some machines have, for example, two Keystone rings or an "L" shaped top and Keystone lower ring. Single-ring pistons generally have an "L" shaped ring fitted.

7. Check ring side-clearance where specified. (Refer to the Specifications charts).

8. Check ring end-gap. Free end-gap is specified for some machines and is meant to determine whether the ring has lost tension or has been deformed through use.

Installed end-gap is checked by inserting the ring about ½ inch into the bottom of the bore. Check that the ring is contacting the bore at all points. If not, either the ring is deformed, or the bore is worn.

End-gap specifications are given in the charts at the end of this section.

9. The connecting rod small end needle bearing can be removed from the rod by hand, on models so equipped.

10. Needle bearings exhibiting flat spots or pitting on the rollers or races should be replaced along with the wrist pin.

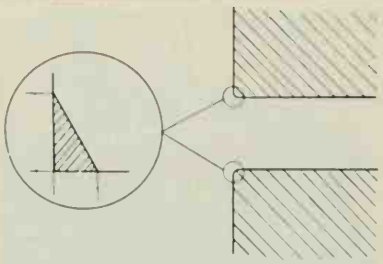
11. Check the vertical play of the wrist pin in the rod small end. There should be no noticeable play. Maximum is 0.045 mm (0.002 in.). If it is in excess of this, the bearing and pin should be replaced.

12. Lightly oil the wrist pin and insert it into the piston. The pin should be a snug push fit. Note the amount of drag on the pin while attempting to push it in by hand. If the pin goes in easily, or can be easily turned after insertion, either it or the piston will have to be replaced.

13. To check for connecting rod straightness, fit the piston, minus the rings, onto the connecting rod and install the wrist pin. Install the clyinder. The piston should be dead center in the cylinder bore. If moved to either side, it should return to the center position after the engine is turned over once or twice. If it does not, or if it appears to be to one side or the other in the bore, the connecting rod is bent.

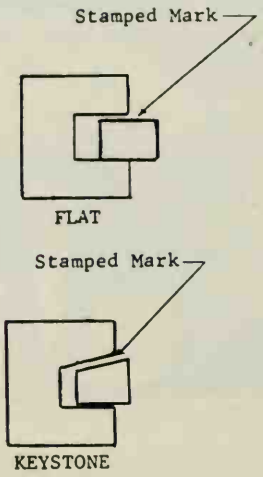
CYLINDER HEAD, CYLINDER, AND PISTON

Assembly



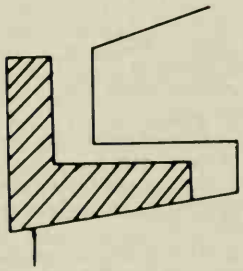
1. Assemble the piston and rings. Models which use only one keystone or "L" shaped ring will have this ring in the top groove.

Models with an "L" shaped ring and a keystone ring will have the "L" shaped ring in the top groove.



Models using two keystone rings have the rings marked with a number (1 or 2) and a letter: "1N," "2N," etc. The number is the ring position. "1" is the top ring, and "2" is the bottom ring.

Models with two plain rings will have the chrome-plated ring installed in the top piston groove.

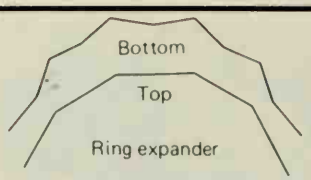


Due to the fact that the piston grooves are shaped to accommodate the shape of the ring, it is important to install rings in their proper locations.

After boring, a slight chamfer must be put on the edges of all ports

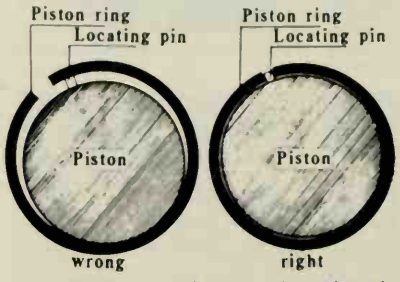
Comparison of the plain and "keystone" type piston rings and their grooves (Courtesy Yamaha Int. Corp.)

Cross section of an "L"-shaped ring



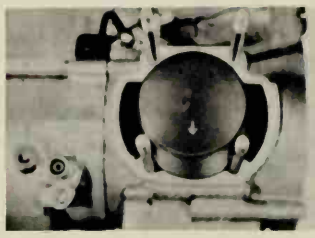
All rings are installed with the stamped mark facing *up*.

Install the ring expanders, if fitted, on the piston. Note that the expanders may be different for the top and bottom rings.



Spread the ring ends with your thumbs, while moving the other end of the ring down onto the piston. When the rings are in their proper groove, align the ring ends with the locating pin in the ring groove. Be sure that the rings are in this position when the piston is inserted into the bore.

2. Lubricate the connecting rod small end with two-stroke oil. Place the piston over the rod with the arrow on the piston crown pointing toward the *exhaust* port.



If the piston is equipped with induction holes in the piston skirt, make sure that they face rearward, toward the intake ports. Push the wrist pin into the piston until it is located between the snap-ring grooves.

Be sure that the ring ends are seated on either side of the locating pin

Install the piston so that the arrow on the crown points towards the exhaust port (Courtesy Yamaha Int. Corp.)

3. Install *new* wrist pin snap-rings.

4. Clean off the crankcase mating surface and fit a new cylinder base gasket. Check again to ensure that the piston is correctly installed and that the ring ends are on either side of the locating pins.

5. Lubricate the piston rings and skirt with two-stroke oil. Place the piston at top dead center. Move the cylinder down over the piston until the piston begins to enter the bore. Then carefully compress the rings with your fingers until they enter the bore. Continue moving the cylinder downward until it is seated in the crankcase.

6. If cylinder studs are fitted, install the nuts and tighten in a cross pattern in increments of 5 ft lbs until the specified torque is reached.

7. Clean off the top of the cylinder. Apply some clean oil to both sides of the head gasket and install it on the cylinder. "Top" is marked on some head gaskets.

8. Clean the threads of the cylinder head bolts or studs. Fit the head and tighten the fasteners in a cross pattern in increments of 2–3 ft lbs until the proper torque is reached.

9. The remainder of the procedure is the reverse of removal. Use new exhaust pipe gaskets where applicable.

Left Crankcase Cover and Components

The following section covers the re-

moval, inspection, and installation of the magneto or generator (depending on model), clutch release mechanism, and countershaft sprocket.

Note the following points:

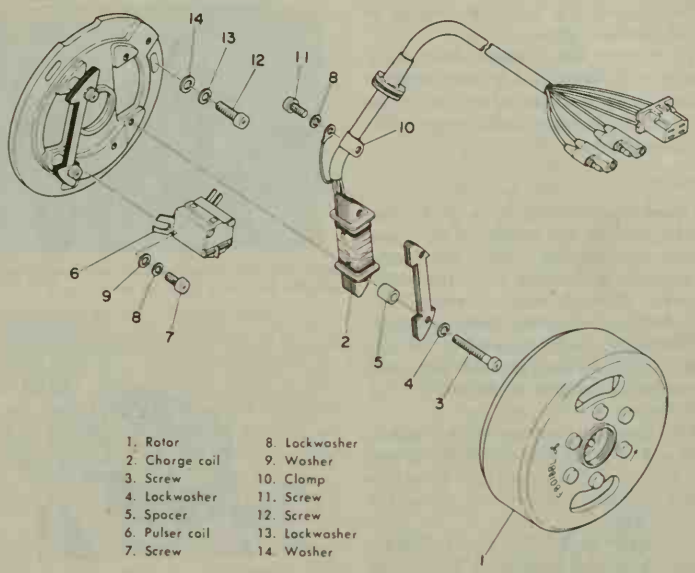
1. A puller is absolutely necessary to remove the magneto rotor, and a puller bolt is also needed to remove the armature on generator-equipped models. In addition, it may be necessary to use a rotor holder to remove the rotor nut on magneto bikes.

2. Electrical tests of the magneto or generator components can be found in the "Electrical Systems" section.

LEFT CRANKCASE COVER

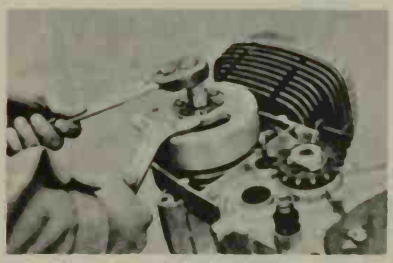
1. Loosen and completely remove the shift lever pinch-bolt. Slide the shift lever off its splined shaft.

2. Using an impact driver, remove the screws securing the cover.



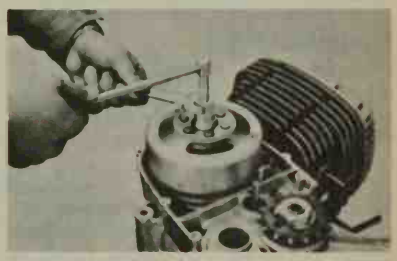
3. Remove the cover from the crankcase. If the cover is stuck, tap it lightly with a rubber mallet. If the cover gasket is not damaged it may be reused. Be careful not to nick the gasket surface.

NOTE: *On some models, the cover can be removed in halves, to expose the magneto or the countershaft sprocket. It is necessary to remove only the half shielding the component to be worked on. If only the magneto cover is to be removed it is not necessary to remove the shift lever.*



MAGNETO

Removal and Installation



1. On models with a split left-side crankcase cover, remove the front half. Remove the whole cover on models with a solid cover.

2. Hold the magneto rotor and remove the securing nut. It is a normal right-hand thread. An impact driver may be used to remove the nut while holding the rotor with your hand. Alternately, placing the machine in gear and applying the rear brake may enable you to remove the rotor nut.

Magneto components (Courtesy Yamaha Int. Corp.)

3. If the engine is not in the frame, the countershaft sprocket can be secured by looping a length of old drive chain around it and securing the ends of the chain in a vise. Engaging the transmission will then effectively lock the rotor in place so that the nut can be removed.

4. Use the special puller to remove the magneto rotor. Back the puller bolt off several turns so that the puller can be threaded a good way into the rotor. Thread in the puller (left-hand thread). When it is in as far as possible, hold the puller with a wrench and turn the puller bolt clockwise until the rotor comes off the crankshaft.

NOTE: *If the rotor resists removal, tighten the puller bolt as much as possible, then give the end of the bolt a sharp rap with a hammer, which should break it loose.*

CAUTION: *Do not strike the rotor itself. Do not hit the bolt hard enough to damage the tapered shaft. Never try to pry or otherwise force the flywheel off its tapered shaft. Do not strike the tapered shaft as this will mushroom or bend the threaded portion.*

5. Remove the woodruff key from the shaft to keep from losing it.

6. Disconnect the magneto wiring at the back of the engine.

7. To remove the magneto base plate complete with coils and points, remove the three or four securing screws at the perimeter of the plate and lift the plate from the engine.

Inspection

1. Check the rotor for loose hub rivets or cracks. Check the inside of the rotor and note any scoring which may have been caused by contact with the stator coil cores. If such scoring exists, the cause must be determined and remedied.

2. Check the stator assembly for any damage visible to the eye such as scored coil core ends, broken or frayed wiring, loose coils, etc.

3. The tapered portion of the crankshaft should be smooth and free of corrosion, rust, etc. Finish off any scratches or scores with fine emery cloth. Clean the area thoroughly.

4. Check the end of the crankshaft for play which would indicate a bad crank bearing. This is one thing which would cause the rotor to strike the coil cores.

Installation

1. Installation is the reverse of removal. On some models, the magneto plate has slotted mounting holes. Install the plate so that the mounting screws are centered in the slots.

2. Do not forget to install the woodruff key. Apply some oil or grease to the crankshaft taper to facilitate removal next time.

3. Push the rotor on by hand after lining up the rotor slot with the key.

4. Use the rotor nut to drive the rotor home. Do not strike the rotor. Torque the rotor nut to the proper specification.

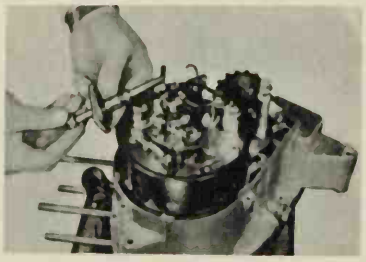
5. Set the ignition timing.

GENERATOR

Removal and Installation

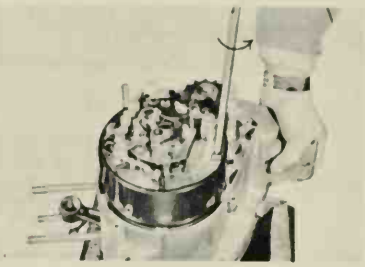
1. Remove the left-side crankcase cover. On models so equipped, remove only the front half of the cover.

2. Label and disconnect all generator wiring at the stator terminals.



3. Remove the slotted armature bolt securing the points cam and advance mechanism to the crankshaft.

4. Remove the stator securing screws at the edge of the stator assembly and remove the assembly complete with the points and brushes.



5. Using an armature puller or slide hammer, remove the armature from its keyed tapered shaft.

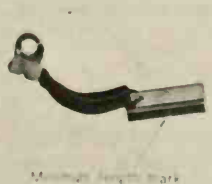
6. Remove the woodruff key to prevent loss.



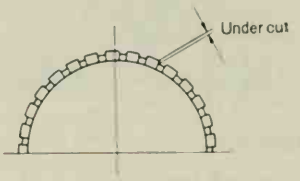
7. Installation is the reverse of removal. The tapered shaft may be lubricated with a very light coat of grease to ease future removal. The point gap and engine timing will have to be reset. When reinstalling the stator assembly, be careful not to damage the brushes.

Inspection

1. Check the brush length and condition.

2. There is a mark on the brush indicating minimum length. Replace the brushes if worn too short. Three-quarters of the brush contact surface area must contact the commutator.

3. When replacing the brushes, make sure that the lead to the positive brush does not ground out on the breaker plate or the brush holder.



Check the carbon brushes for wear. Minimum length is usually marked (Courtesy Yamaha Int. Corp.)

4. Clean the commutator of carbon, oil and dirt. The commutator may be polished with 400 sandpaper or crocus cloth. The commutator must be completely round and devoid of flat spots. Do not remove excess metal with the sandpaper. Flat spots may be identified by irregularly shaped darkened areas spanning several commutator bars.

5. Inspect the generator armature for wear or scoring of the commutator segments. If the armature has been rubbing against the stator, the cause must be determined. This may be caused by an improperly mounted stator, a bent crankshaft, damaged crank bearing, etc. When the armature rotates it must not touch the stator at any point. The commutator may be turned on a lathe to remove any out of roundness or flat spots. A maximum of 2 mm may be removed from the standard 40 mm commutator diameter.

6. After the commutator is turned or cleaned, it will be necessary to remove metal and carbon deposits between the metal commutator bars. Clean the grooves with the broken end of a hacksaw blade. The groove must be kept square shaped.

Commutator undercut (Courtesy Yamaha Int. Corp.)

CAUTION: *Never clean a commutator groove with a pointed instrument. Be sure that the groove does not have a thin sliver of insulator against one of the commutator bars.*

Commutator undercut should be 0.5–1.0 mm (0.02–0.04 in.).

CLUTCH RELEASE MECHANISM

The clutch release mechanism is located in the left crankcase cover. This mechanism, although seemingly out of the way, is subject to a great deal of grit and corrosion carried in by the chain. If excessive effort is necessary to operate the clutch, it may be necessary to remove and clean the mechanism.

1. Remove the small mechanism cover and then remove the crankcase cover. When removing the crankcase cover, be careful not to lose the small ball bearing in the mechanism.

2. Disconnect the clutch cable.

3. Loosen the adjuster locknut and turn the adjuster screw out of the cover.

4. Turn the release mechanism out of the crankcase cover.

5. Clean the mechanism in a solvent and reinstall it in the cover. Upon reinstallation, lightly lubricate the mechanism with grease. Excessive amounts of grease will cause rapid build-up of dirt.

6. Readjust the clutch.

COUNTERSHAFT SPROCKET

Removal and Installation

1. Remove the left crankcase cover, or

the rear half of the crankcase cover, if so equipped.

2. Flatten the bent edge of the sprocket nut lockwasher with a cold chisel.

3. Holding the sprocket by applying the rear brake hard, loosen and remove the sprocket securing nut. An alternate method of holding the sprocket is to put the transmission in First gear and use an impact wrench to remove the nut.

Right Crankcase Cover and Components

Included in the following section are the primary drive gear, clutch, gearshifter shaft, kick-starter mechanism, rotary valve, and tach drive gear.

RIGHT CRANKCASE COVER

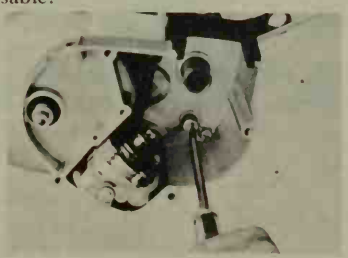
Removal and Installation

NOTE: *The right crankcase cover may be removed while leaving the oil pump in place if desired.*

1. Remove the kick-starter lever pinch-bolt and pull the lever off the splined shaft.

2. Drain the transmission oil.

3. Remove the oil pump and carburetor covers. On rotary valve machines, remove the carburetor as outlined in "Fuel Systems." Disconnect the air cleaner hose.



4. Disconnect the oil feed line at the oil tank and plug the tank outlet.

5. Disconnect the oil pump cable from the pump and the adjuster holder or adjuster from the cover. Disconnect the oil pump feed line from the engine. On piston port models, this is on the cylinder or manifold; on rotary valve engines it is located in the oil pump compartment (see the illustration). Cover the banjo bolt and washers with a plastic bag to prevent the entry of dirt.

6. Place a drip pan beneath the cover to catch any oil residue. Loosen all of the phillips head cover screws with an impact driver and remove them. On some models there is a screw in the oil pump compartment. Tap around the edges of the cover with a plastic mallet to free it, if stuck, and remove the cover. Pull off the cover gasket.

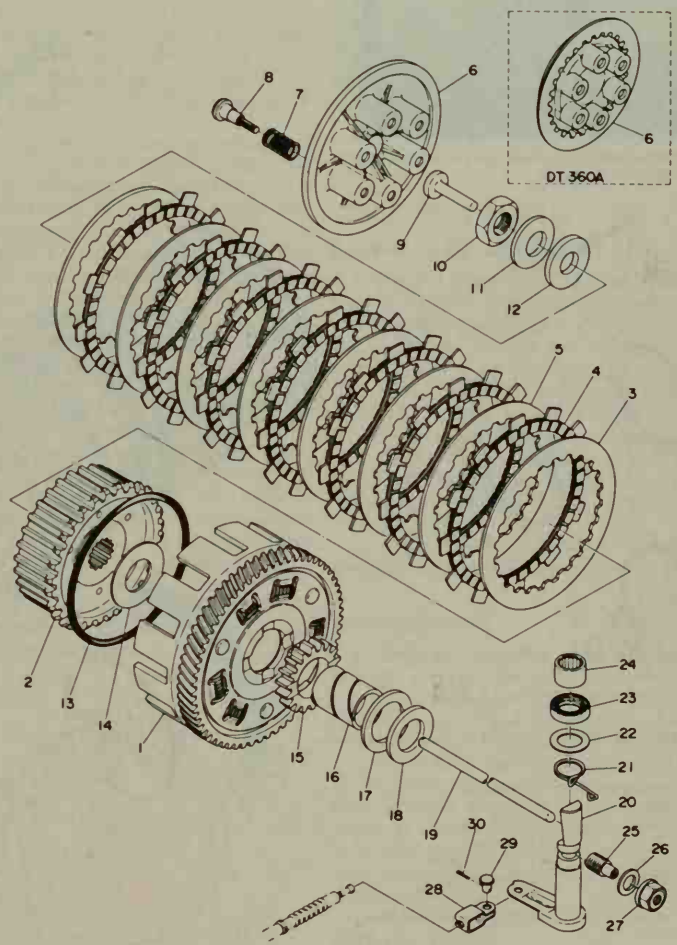
7. When installing the cover, use Yamaha Bond #5 on both mating surfaces.

8. It is sometimes helpful to grease the kick-starter shaft before installing the side cover to minimize chances of rendering the kick-starter shaft oil seal unusable.

Disconnecting the oil pump feed line (rotary valve models) (Courtesy Yamaha Int. Corp.)

9. On models which have the oil pump driven directly off the crankshaft, be sure that the pump driveshaft engages its hole in the end of the crank. If the shaft had remained in place when the cover was removed, carefully rotate the oil pump with the starter plate while fitting the pump so that the oil pump gear engages the shaft worm gear. Do not attempt to force the cover into place.

CLUTCH



Removal

NOTE: *If the primary drive (crankshaft) gear is to be removed later, it is advisable to loosen the primary drive gear nut with the clutch installed. Stuff a rag between the clutch and primary gears to lock them in place, then loosen the nut. Using impact rather than steady pressure on this nut will make removal easier.*

Removing the clutch hub nut requires some method of holding the hub in place. This can be accomplished with a tool which may be fabricated by welding a hefty handle onto an unused steel clutch plate. Other methods which can be used are: if the engine is in the frame, engaging the transmission and applying the rear brake; if out of the frame, engaging the transmission, looping a length of old drive chain around the countershaft sprocket and locking the ends of the chain in a vise; using an impact driver on the nut may also be effective.

1. Remove the right-side cover.

2. Loosen the clutch pressure plate screws gradually and evenly, then remove them, the pressure plate, and the

3. Remove the clutch pushrod. If the engine is on the bench, note that there is a ball bearing behind this outer pushrod which will come out if the engine is tilted.

4. Remove the clutch steel and friction plates on some models. Handle them carefully. Note the order of the plates and bands as they are removed. All components must be installed in the same order.

5. Remove the clutch hub nut using one of the methods suggested above.

6. Remove the clutch hub. Note the presence of any thrust washers or shims behind the hub.

7. It is now possible to slide the clutch housing and gear assembly off its shaft. Note that there is one or more of the following behind the housing assembly: kick-starter pinion gear, thrust washers, or needle bearing. These are very close tolerance parts and they should be kept very clean.

CAUTION: *All thrust washers or shims in the clutch assembly must be labeled and installed in their original locations. In most cases, the washers are not interchangeable. Thickness may vary, and if incorrectly installed will impair clutch operation.*

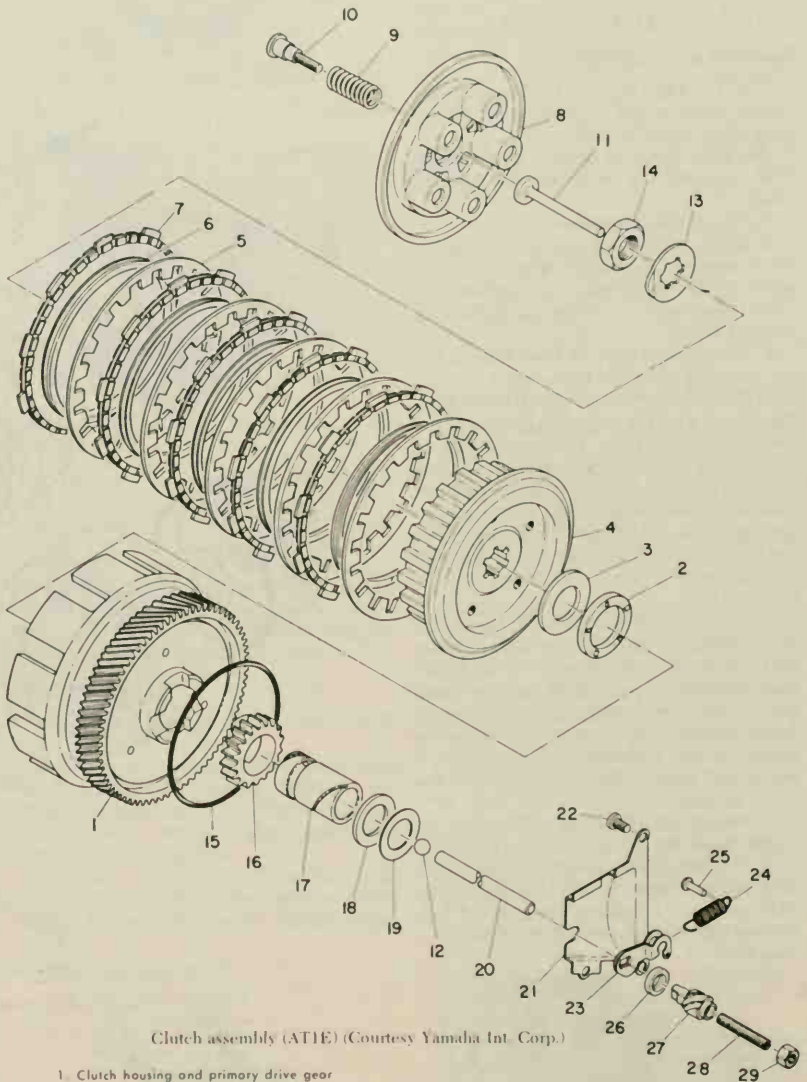
Inspection



1. Refer to the "Clutch Specifications" chart at the end of this section for individual models.

2. Check spring free length and replace the set if any spring is 1.0 mm (0.04 in.) or more under the standard specification.

3. Check friction plate thickness.

4. Check steel plate warpage. Maximum allowable warpage is 0.2 mm (0.008 in.) for 175 cc and smaller machines before 1975, and 0.05 mm (0.002 in.) for 175 cc and smaller machines 1975 and later and 250–400 cc bikes, all years.

5. Remove the bushing from the housing and inspect both inner and outer surfaces for scoring, scratches, or wear. Remove any such imperfections with emery cloth or sandpaper. If the damage

cannot be remedied in this way, replace the bushing.

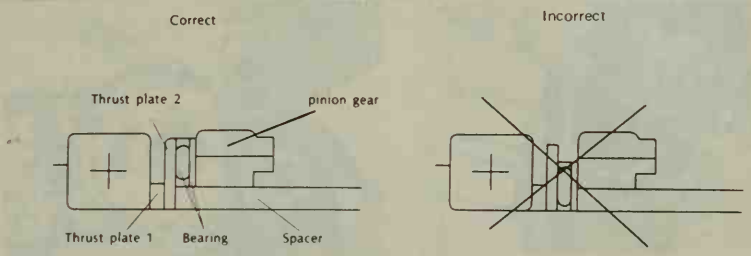
6. Insert the bushing into the housing and check for play. If the clearance is excessive, replace the bushing. If a new bushing yields an excess of play, replace the housing. The bushing should be a smooth press fit; it should rotate easily. Proper clearance is 0.009–0.048 in. (0.23–1.2 mm).

Checking the bushing for excessive play in the housing (Courtesy Yamaha Int. Corp.)

7. Place the bushing on the mainshaft. If excessive play is noted here, the bushing should be replaced. Normal clearance is 0.020–0.060 in. (0.5–1.5 mm).

A worn or scored bushing will cause excessive clutch noise and possibly impair operation.

8. If, after the above checks are performed, the clutch drags or fails to engage completely, check the condition and thickness of the thrust washers. If the thrust washers are galled or found to be too thick because of installation of new parts, there will be insufficient end-play between the clutch gear assembly and the clutch hub. Install new or thinner washers. If the thrust washers are too thin, excessive end-play will be apparent causing too much movement of the clutch assembly on its bushing or failure to disengage.



9. Check the long pushrod inside the transmission mainshaft. If may be removed by tilting the engine and letting it slide out. Do not lose the ball bearing inside the mainshaft (if fitted). Roll the pushrod on a flat surface to make sure that it is not bent. Replace if necessary. Replace the ball bearing if it is dented or damaged.

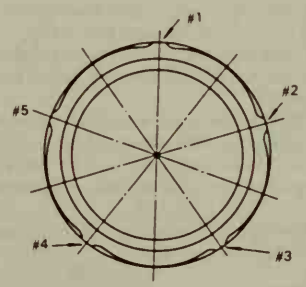
Installation

1. The installation of the thrust washers in their original locations is critical. Note that in most clutches, these washers are found on either end of the clutch hub bushing. It is possible that a thrust washer fitted onto the transmission shaft may slip down while the bushing is being installed. This will impair clutch operation. All thrust components should be held in place with bearing grease or the like.

Exercise caution when fitting the clutch that the thrust washers are correctly positioned (Courtesy Yamaha Int. Corp.)

2. Assemble the plates and cushion rings (if fitted) onto the hub. Then install the hub. Make sure that the cushion rings are not twisted during installation. Be sure that the hub O-ring (if so equipped) is in place.

3. Late models clutches have modified steel plates to reduce clutch noise. The plates have a cut-out on the edge with a small tab. Install these plates in the following manner:



a. Install the first steel plate so that the tab aligns with the arrow on the clutch hub.

b. Install a friction plate. Install the next steel plate so that the tab is about 60° from the first.

c. Continue around the clutch, installing the steel plates so that the tabs are spaced apart equally.

4. When installing the pressure plate, the spring screws must be tightened gradually and evenly. On late models, the pressure plate and clutch hub are marked with arrows. The pressure plate must be installed so that its arrows align with those on the hub.

5. After installation is completed, adjust the clutch and clutch cable as outlined in "Maintenance."

A rolled up rag between the clutch and primary gear teeth will jam the gears so that the primary gear nut can be removed (Courtesy Yamaha Int. Corp.)

CRANKSHAFT PRIMARY GEAR

Removal and Installation

1. Feed a thick rolled up rag between the teeth of the primary gear and the primary driven (clutch) gear. This will jam the gears and enable the primary gear securing nut to be loosened.

2. Remove the nut and washer and remove the gear by prying it off as shown. Do not use the crankcase as a lever point.

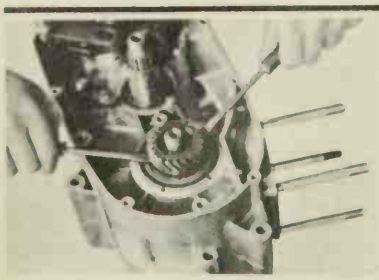
3. Check the shoulder on the gear where the crankshaft oil seal rides. If the shoulder is galled or has a deep groove, replace the gear.

4. Check the O-ring on the crankshaft, if equipped, for damage or stretching.

Lash Tolerance

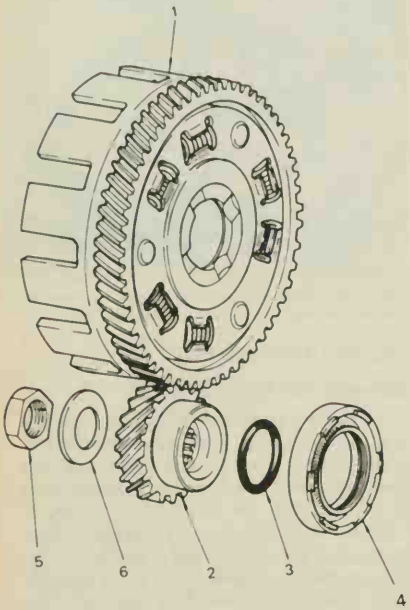
1. If the primary gear must be replaced due to obvious damage, note the lash number stamped on the gear. Replace the gear with another of the same number, or refer to the following specifications.

2. Lash tolerance is obtained by adding the lash numbers of the primary drive and primary driven (clutch housing) gears. If the sum of the two numbers is less than the minimum, excessive wear will occur. If greater, noise will be the result.



ROTARY VALVE

Removal



1. Remove the engine side cover, primary drive gear, and clutch assembly as outlined in the preceding sections.

3. Remove the rotary valve and the rotary valve collar.

4. Remove the rotary valve locating pin from the crankshaft either by pulling it out with pliers or by tapping it out.

CAUTION: *Take care not to damage the crankcase or rotary valve mating surfaces during this operation.*

5. Remove the O-ring from the crankshaft and discard it; a new one must be fitted on assembly.

Inspection

1. The rotary valve must be close to perfectly flat. If warped, replace it.

2. Inspect the valve collar for step-wear caused by the valve locating pin. Replace the collar if wear shows at this point.

Check the collar for step-wear caused by the pin (Courtesy Yamaha Int. Corp.)

3. Insert the collar into the valve. If play is excessive, replace the collar.

4. Place the collar onto the crankshaft; if play is excessive here, the collar must be replaced.

5. Remove any score marks from the collar surfaces with emery cloth.

6. Check the cover oil seal for cracked or damaged lips and replace it if necessary.

7. Replace the locating pin if it is bent or damaged in any way.

Installation

1. The crankshaft and rotary valve cover O-rings should be replaced if they have been disturbed. The valve cover O-ring must be replaced if it will no longer fit properly in its groove.

2. Grease the O-rings thoroughly before installing them. The valve cover O-ring should be seated in the cover groove. The crankshaft O-ring should be located in the crankshaft groove.

3. Grease the lips of the valve cover oil seal before installing the cover.

KICK-STARTER MECHANISM

On some models it is necessary to remove the clutch assembly before the kick-starter mechanism can be removed. The clutch must be removed to take off the kick-starter idler gear.

Three basic types of kick-starters are fitted depending on model and year. Refer to the correct procedure for your model.

Removal and Installation

Older Type

This type of kick-starter assembly was fitted to most models 1968–1973 except for 1971 and later DT and RT machines.

1. Remove the kick-starter lever and the right crankcase cover.

2. On models where the kick-starter gear will not clear the clutch, remove the clutch assembly.

3. Disconnect the kick-starter return spring from the crankcase.

4. Lift out the kick-starter shaft and gear assembly, noting the position of any thrust washers. The kick-starter mechanism may be disassembled by removing the circlip at either end of the shaft.

5. To remove the idler gear, remove the clutch assembly (if still in place). Then remove the idler gear circlip and slide the gear off its shaft.

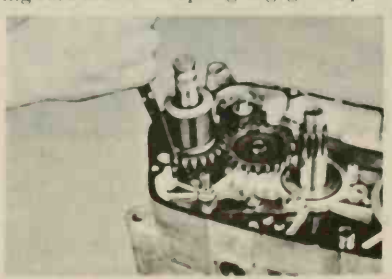
6. Installation is the reverse of the removal procedure. The wishbone clip projection must be seated in the crankcase recess.

Non-Constant Mesh Type

This kickstarter is used on DT100, 125, and 175 models as well as late GT machines.

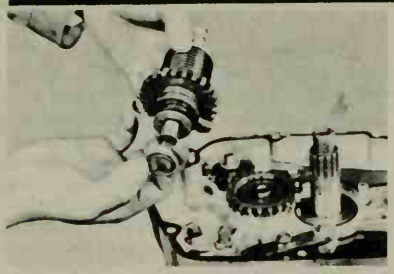
1. Remove the kickstarter lever and right crankcase cover.

2. Remove the clutch assembly.



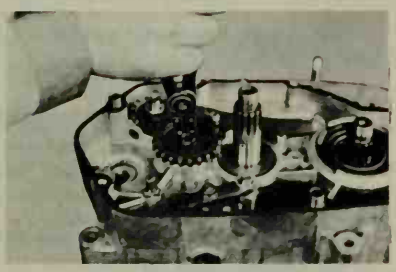
3. Disconnect the kickstarter return spring from the pin.

4. Rotate the kickstarter shaft counterclockwise and pull it out. Remove the idler gear circlip and take the gear off its shaft.



5. Disassemble the shaft by removing the circlip.

6. When assembling, install the kickstarter gear so the side with the chamfered tooth edges faces the return spring.



7. Install the components on the shaft. Temporarily fit the starter crank. Holding the shaft stopper vertically, engage the return spring with the slot at the end of the shaft. Turn the shaft counterclockwise about ¾ of a turn and push in, making sure the return spring engages its pin.

Ratchet-wheel type kickstarter assembly (Courtesy Yamaha Int. Corp.)

Ratchet Type

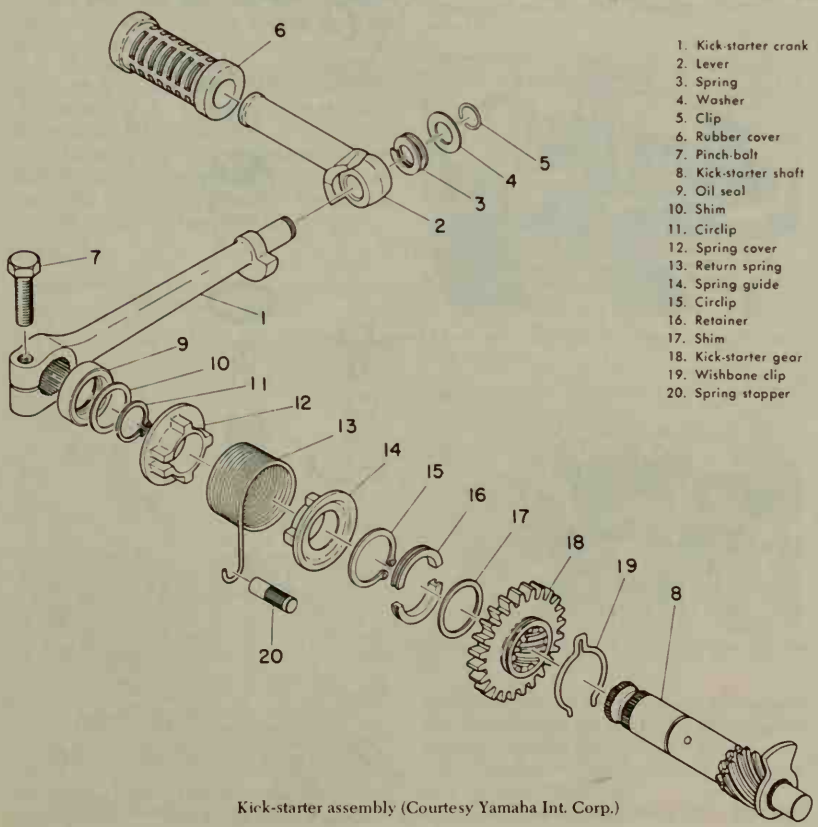
This mechanism uses a ratchet wheel to engage the idler gear, and is fitted to 250–400 cc machines after 1971.

1. Remove the kick-starter lever and the right crankcase cover.

2. Remove the clutch assembly if the kick-starter gear will not clear the clutch mechanism. Disconnect the compression release cable, if fitted.

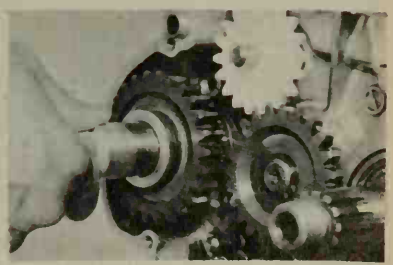
3. Rotate the kick-starter shaft assembly about 45° and pull the assembly out of the crankcase. This will allow the ratchet wheel to clear the guide bolted onto the crankcase as the assembly is withdrawn.

NOTE: *Notice the amount of spring tension on the kick-starter mechanism. The assembly must be installed with the proper amount of tension to ensure proper disengagement of the ratchet wheel.*



4. Disassemble the kick-starter shaft and gear assembly by removing the circlips from either end of the shaft.

5. Removal of the idler gear is accomplished by removing the circlip.



6. Upon installation note that the return spring fits into the machined groove in the end of the kick-starter shaft.

7. Before inserting the assembly into the crankcase, align the marks on the ratchet wheel and the shaft.

8. As the kick-starter assembly is inserted, slide the ratchet wheel pawl over the ratchet wheel guide and onto the stopper attached to the case. Be sure that the pawl is in close contact with the stopper. Now pull the return spring forward and hook it onto its pin.

Inspection

ALL MODELS

Follow the inspection procedures applicable to your model.

1. Check the splines on the kick-starter shaft. If torn, worn, or splintered to the extent that they will not hold the kick-starter lever in place, replace the shaft.

2. Check the gear teeth on the shaft. If any are broken or worn, the shaft should be replaced.

3. Check the condition of the ratchet wheel on models so equipped. The inside gear teeth should be in good condition. Replace the gear if they are worn or broken. The ratchet wheel should be fairly loose on its splines but not so loose that it cocks and jams. Make a close inspection of the ratchet teeth (on the side of the gear). The gear must be replaced if these show signs of wear. If they are worn, check the condition of the ratchet teeth on the kick-starter gear in the same manner. Replace this gear as well if the teeth are worn.

4. If the kick-starter gear has a plain bore, check it for scoring and finish up any defects with a fine emery cloth. Check that the gear does not have excessive play on the shaft.

5. Check the kick-starter gear teeth for wear, chipping, and other damage, and replace the gear if the teeth are damaged.

6. Inspect the kick-starter idler gear in the same ways (Steps 4–5). The idler gear must spin freely on its shaft without excessive play.

7. If the early-type kick-starter mechanism is fitted, check the inside surfaces of the kick-starter gear. If the internal splines are worn or chipped, replace the gear.

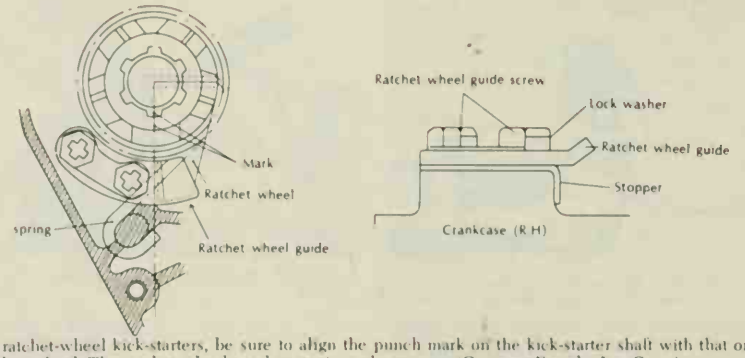
8. Check the wishbone clip and replace it if twisted or deformed.

9. Check the condition of the kick-starter return spring. If the spring has fatigued or twisted ends, it should be replaced. If the kick-starter lever returns slowly or fails to return completely, replace the spring.

10. Replace any broken or twisted circlips.

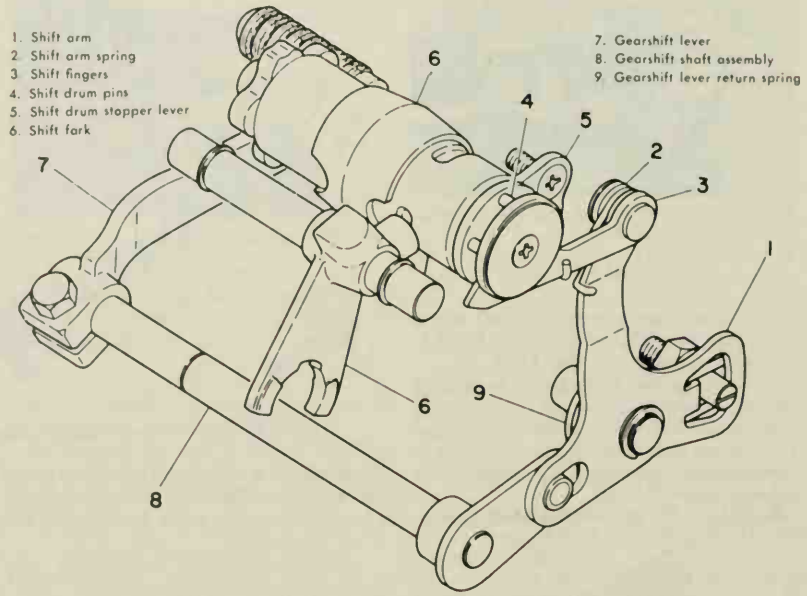
11. Check the kick-starter shaft for wear in any area a gear rides on. Insert the shaft into its bushing. If there is excessive play, either the shaft or the bushing should be replaced.

12. On models with a compression release, insufficient free-play will cause the ratchet wheel to hang up and jam the starter mechanism.



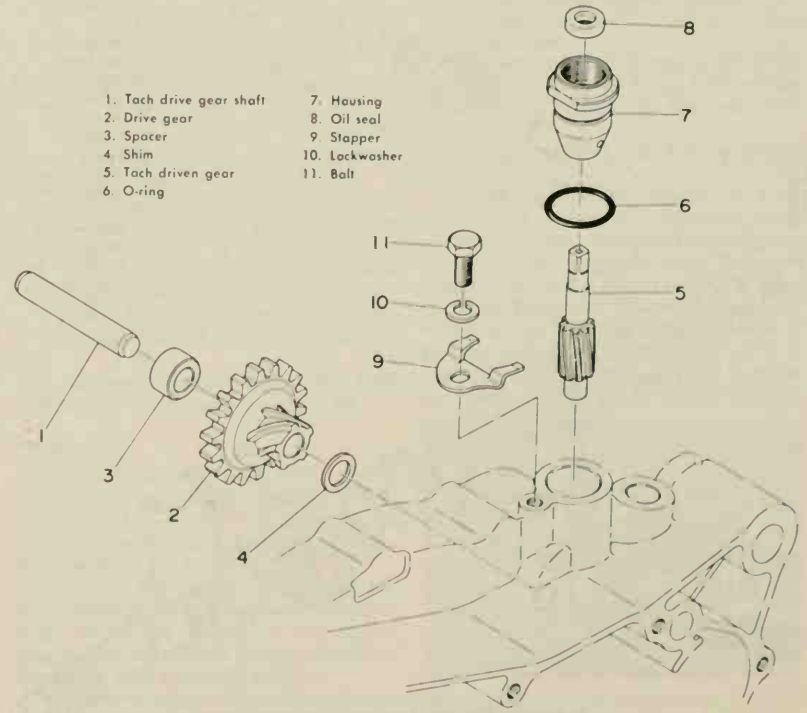
13. On models equipped with a ratchet wheel, check the ratchet wheel spring length. It should be 15.0–17.2 mm.

TACHOMETER DRIVE GEARS



Removal and Installation

1. The tachometer driven gear may be removed from the right crankcase without removing the cover. Remove the bolt holding the C-shaped clamp to the crankcase.



2. Pull the stopper out of the case,

TRANSMISSION SHIFTER SHAFT

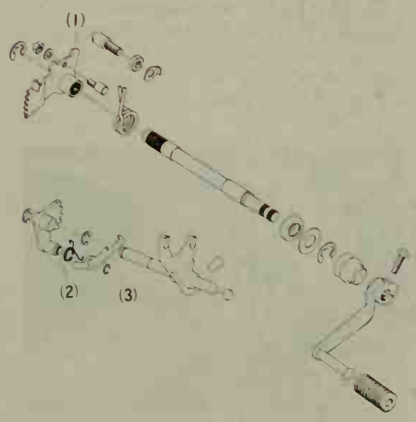
The gearshift lever is located on the left-side of the engine and is connected by a shaft to the shifter mechanism located beneath the right crankcase cover. The shifter mechanism is accessible for service after removing the crankcase cover and the clutch assembly. The shift drum, forks, etc., are housed in the crankcase, and the causes must be split to service these components.

Shift shaft mechanisms are different, depending on model.

Refer to the illustrations to determine which type your machine is equipped with. The ratchet-type is easily identifiable because of the gear teeth on the two shift levers.

Removal and Installation

1. Remove the gearshift lever, the left and right crankcase covers, and the clutch assembly.
2. Remove the rubber boot from the left-side of the shifter shaft, if fitted.
3. Remove the shifter mechanism cover (left side) if fitted, as on DT100 and 175. The lever shaft may come off with the cover. Note shim locations on these models.

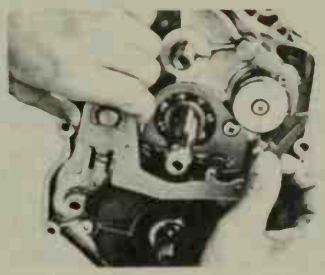


Remove the circlip(s) from the left-side of the shift levers or shifter shaft. On the DT100 and 175, remove the shift levers, lever roller, shims and washer from the left side.

4. Remove any circlip from the right side of the engine which would prevent the shifter shaft and lever assembly from being withdrawn.
5. Disengage the fingers of the spring-loaded shift arm from the shift drum (if necessary) and pull the shifter shaft assembly out from the right side.
6. On ratchet-type shifters, remove the remaining ratchet gear circlip, disengage the fingers of the shift arm from the shift drum and pull off the gear.
7. Installation is the reverse of removal. For ratchet-gear type shifters, ensure that the punch mark on the 5-tooth gear is positioned as shown.

Inspection

Follow those procedures applicable to your type of shift mechanism.



1. Check the splines on the gearshift shaft for wear or splintering, and replace the shaft if they are too badly damaged to properly secure the gearshift lever.
2. Check the shaft for a bent condition and replace it if bent.
3. Check the shift arm for straightness. Check the shift fingers for straightness, and especially for wear at the tips.
4. Inspect the shifter return spring and replace it if broken, or if the ends of the spring show signs of twisting or fatigue.
5. Check the other springs in the shift linkage and replace any that are deformed or damaged. There should be no free-play in the linkage. If play exists, check for weak or broken springs and replace them.

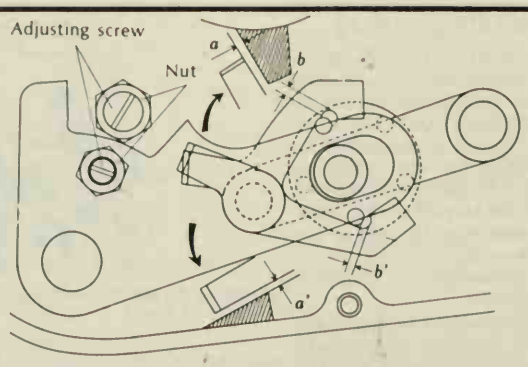
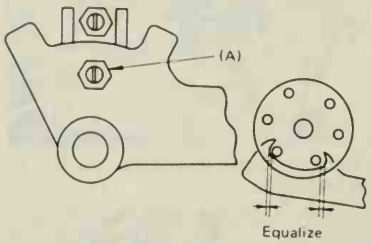
Adjustment

The adjustment procedure will vary according to the type of shift linkage fitted. Some mechanisms require two adjustments be made, others only one.



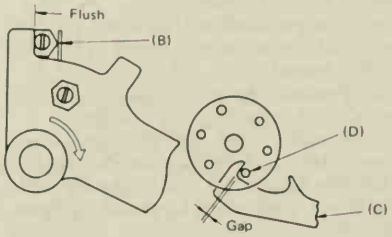
Where a simple double-change shaft mechanism is fitted, only one adjustment is necessary. Refer to the accompanying illustration. Loosen the locknut and turn the adjusting screw so that the distances "A" and "A'" are equal.

Where two adjusting screws are fitted (one on the shift arm plate and the other on the crankcase), adjust as follows: first adjust the smaller adjusting screw on the shift arm plate so that the distances "a" and "a'" as shown in the illustration are equal. Then use the crankcase-mounted adjuster so that distances "b" and "b'" are equal.



For ratchet-gear type shifters, proceed as follows:

a. Place the transmission in Second or Fourth gear. Check the distance between the two fingers of the shift arm and the shift drum dowel pins. The distances should be equal. If adjustment is necessary, use adjusting screw "A" in the illustration to effect equalization.



b. Place the transmission in Third or Fifth gear, and hold the shift lever down so that the stop on the shifter ratchet gear abuts against the adjusting screw "B" in the illustration. Measure the gap between the shift arm "C" and the drum dowel pin "D." Shift the transmission down one gear to either Second or Fourth, hold the shift lever down and check the gap again. Use adjusting screw "B" if necessary so that the gap is equal in both cases.

The smaller adjusting screw is used to equalize distance "a" and "a'"; the larger for "b" and "b'" (Courtesy Yama Int. Corp.)

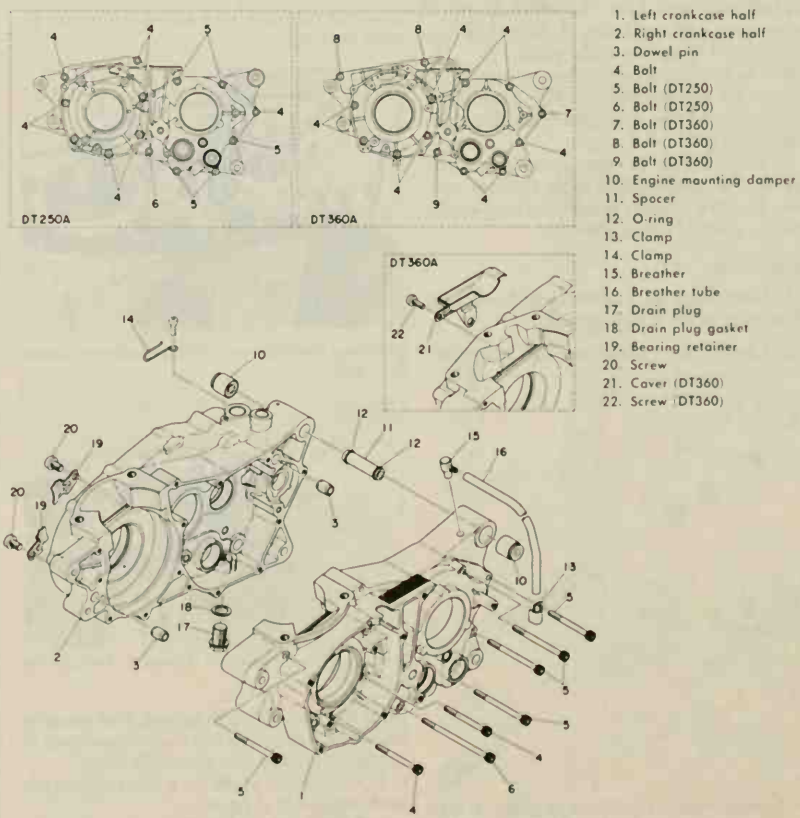
Lower End and Transmission

The following section deals with service to the crankshaft, transmission, shifter assembly (drum), crankcase bearings and seals. Removing the engine from the frame and splitting the crankcases is necessary to service these components.



Adjust the shifter so that distance "A" and "A' " are equal (Courtesy Yamaha Int. Corp.)

SPLITTING THE CRANKCASES

The crankcases split vertically. Before beginning, have on hand a complete set of engine gaskets, rotary valve O-rings (if applicable), and transmission and crankshaft seals.

In addition to special tools needed to remove the components already covered, a jig is necessary to split the cases. Tapping the cases apart is not recommended.

3. Remove the neutral stopper bolt, spring, and plunger. Remove the gearshift drum stopper, spring and lever (if fitted). Remove the shift guide (if equipped). Remove any bearing retainer plates.

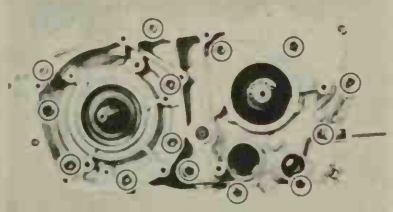
4. Loosen each crankcase screw or bolt ¼ turn, then remove them. Fit the crankcase separating jig to the right case half, and tighten the jig bolt, while tapping lightly on the end of the mainshaft with a plastic mallet. Separate the cases gradually and evenly. Be sure that the jig remains perpendicular to the case.



5. The crankshaft and transmission components will remain in the left case half.

6. Remove the one or two shift fork shafts by pulling them out of the case.

7. The shift forks, drum, and gear clusters must be removed and installed as a unit. If the transmission is to be disassembled, mark the location of each shift fork at this point to facilitate assembly.

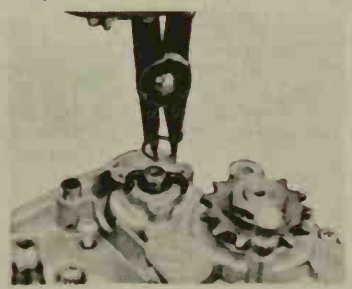
8. Remove the shift drum cover (if fitted) from the outside of the left crankcase half. Remove the drum circlip, washer, and keepers.

9. Tap out the countershaft with a plastic mallet while supporting the gears and shifter assembly with the other hand.



10. Fit the crankcase splitting tool to the left case half, and use it to press out the crankshaft.

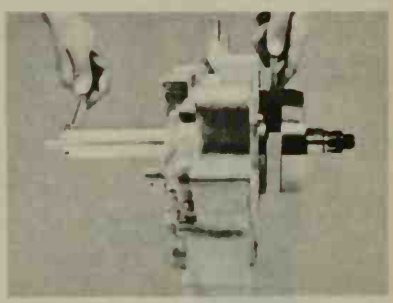
ASSEMBLY

1. When assembling the cases, note the following points:

Removing the crankshaft from the crankcase (Courtesy Yamaha Int. Corp.)



2. Draw the crankshaft into the left case half with the special puller, while holding the connecting rod at TDC.

3. Assemble the shift forks, drum and gear clusters as an assembly. Be sure that the shift drum is positioned in Neutral while refitting the assembly to the cases. The gears and shift assembly must be installed together.

4. Coat the mating surface of the left case half with Yamaha Bond #4. Join the cases with care. Tighten the crankcase screws or bolts securely.

CAUTION: *Do not use the crankcase screws to force the cases together. They should be tightened only after the cases have been mated.*

5. Lubricate all crankshaft and transmission bearings thoroughly before installing the rest of the engine components.

Installing the crankshaft (Courtesy Yamaha Int. Corp.)

6. When installing retainer plates, drum guide or any other component secured with small screws, note that these screws must be firmly tightened. Use an impact wrench or thread locking compound.

CRANKSHAFT

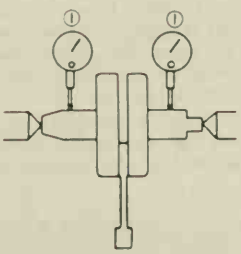
1. Crankshafts on all models are pressed together. To disassemble any crankshaft (which would be necessary in the event of a bent connecting rod, or worn big end bearing), a special tool is needed.

2. Lubricate the big end bearing with two-stroke oil. Rotate the rod slowly around the crankpin. The movement should be smooth and noiseless.

3. With the crankshaft mounted in a jig, and a dial indicator mounted to bear against the small end of the connecting rod, check the lateral movement of the small end. It should not exceed 2.0 mm (0.08 in.). If the movement exceeds this figure, the con rod big end bearing is

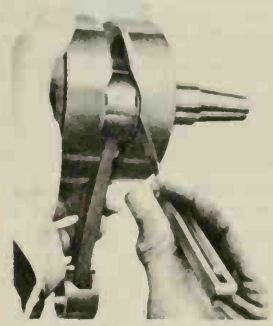
worn, and it must be replaced.

When new, rod small end movement should be 0.8–1.0 mm (0.032–0.040 in.).



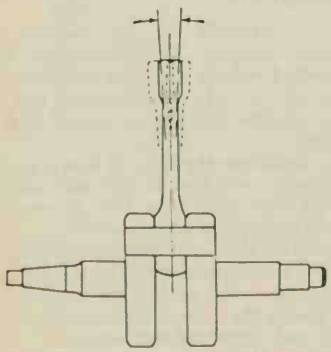
4. Check the connecting rod big end side clearance, with a feeler gauge placed between the rod big end and one of the flywheels. Side clearance should be 0.4–0.5 mm (0.016–0.020 in.). If side clearance exceeds this figure for 250–400 cc machines or 0.6 mm (0.024 in.) for smaller bikes, the crank should be disassembled and inspected for wear to the rod, thrust washers, or flywheels.

5. Mount the crankshaft in a set of V-blocks, and attach dial indicators to each end of the crank.



Rotate the crank slowly, and note the indicator readings. The maximum allowable run-out is 0.03 mm (0.0011 in.). If run-out exceeds this figure, the crankshaft is either bent, or the flywheels are out of alignment.

6. The following procedure concerning crankshaft truing should only be undertaken by an experienced mechanic.



7. The crankshaft must be checked for eccentricity and for parallel fly-

wheels. The crankshaft flywheels are eccentric if one has been rotated slightly ahead of the other. The flywheels are nonparallel if they lean towards or away from each other.

8. Turn the crank in the jig. If the dial gauges do not move the same distance, and do not begin and end their movement at the same time, the crankshaft flywheels are both eccentric and nonparallel. In this event, eccentricity must be taken care of first.

9. To correct eccentricity, rotate the crank until the drive-side dial gauge indicates the high point of its travel. Stop at this point. Imagine a line drawn from one of the dial gauge shafts to the other. Mark the spot on the drive-side flywheel at the spot this line would cross it. Remove the crankshaft from the aligning jig, and, with the brass hammer, strike this spot on the drive-side flywheel smartly. Be sure you are holding the crank assembly by the generator/magneto-side shaft while doing this. Recheck alignment, and repeat this procedure as long as necessary until the dial gauge needles begin and end their travel at the same time.

10. Replace the crankshaft assembly in the jig, and rotate it until the needles reach their highest point of travel. If the crankpin lies along an imaginary line drawn between the ends of the two dial gauge shafts, the flywheels are evidently pinched together opposite the crankpin.

To correct this condition, insert a wedge, preferably of wood or soft metal, between the flywheels at a point opposite the crankpin, and, supporting the crank in one hand, strike the wedge with a hammer to spread the flywheels apart. Continue until the flywheels are parallel within specifications.

11. If, when checking for parallelism, the crankpin was *not* along or near the line drawn between the ends of the dial gauge shafts, if it was opposite this line, then the flywheels are too far apart, opposite the crankpin. In this case, once again make a mark on either flywheel where the imaginary line would cross it. (Note that the crank should be positioned so that the dial gauges are at the highest point of their travel). Remove the crank, and, with the brass hammer, strike the flywheel sharply on the *side* to bring the flywheels closer together. Check again, and repeat the procedure until crank runout is within specification.

12. Clean the crank assembly thoroughly, and oil the big end bearing well.

TRANSMISSION

1. The gears should not be removed from their shafts unless absolutely necessary. If the gears are being removed, be sure that each gear, thrust washer, shim, and snap-ring is laid out in the order of removal so that it can be installed in the proper location.

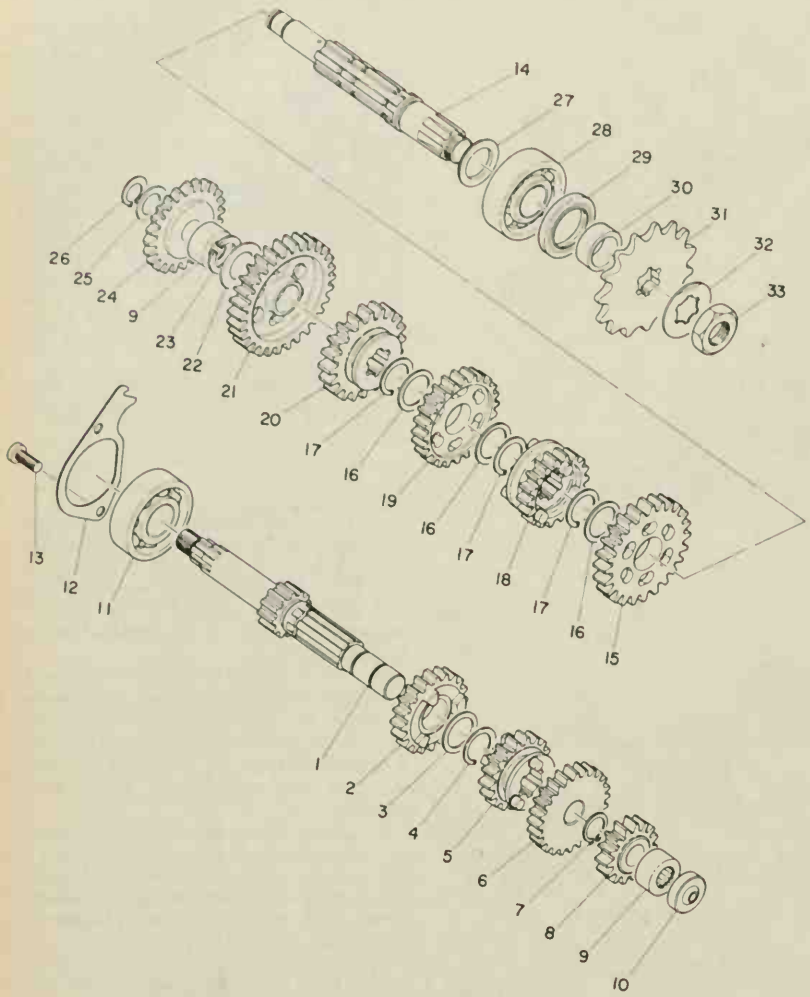
2. Check each of the gears for chipped, broken, or worn teeth. If any gear shows evidence of such damage, it should be replaced. In addition, the gear with which it meshes should be replaced as well, since it has undoubtedly been overstressed.

3. Check the inner splines on those gears so equipped, and replace the gear if the splines are worn or broken. Inspect the corresponding splines on the shafts. Gears with plain bores must show no score marks on the bore.

4. Inspect the engaging dogs on gears which have them. The dogs must not be worn, chipped, or broken.

5. Inspect the transmission shafts for damage to the sprocket nut threads, and wear or damage to the clutch gear, or sprocket splines. Make sure that the shafts are not bent. Inspect the shaft bearings (see below).

6. Check the transmission gears for excessive play on their shafts. If play is excessive, replace the gear.



7. Replace any bent or distorted snaprings or damaged thrust washers. Replacement of circlips which have been removed from the shafts is recommended.

SHIFT DRUM

Machines using the type of shift mechanism in which one or two of the shift forks ride directly on the shift drum may have the forks removed by removing the shift fork cotter pin, pulling out the cam follower pin, and sliding the fork off the drum. Use new cotter pins when assembling.

1. The shift drum itself should be inspected for wear in the shift fork cam follower pin grooves, wear to the cam plate, and scoring or wear of the bearing surfaces.

2. The shift fork shafts should be inspected for wear in those areas on which the shift forks ride. Roll the shafts along a

5. Check the shift drum dowel pins.

BEARINGS AND SEALS

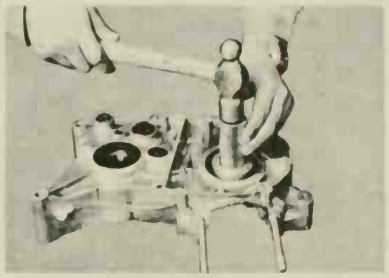
1. Bearings can be checked in place.

2. Lightly lubricate the bearing in question with some motor oil and rotate it slowly. Movement must be smooth, effortless, and quiet.

3. If bearing movement is halting, rough, or noisy, or if the bearing shows discoloration (due to heat) or obvious signs of damage, it should be replaced.

Check the shift drum for wear at the bearing surfaces, cam grooves, and shift cam (Courtesy Yamaha Int. Corp.)

4. Crankshaft bearings should always be replaced in pairs.

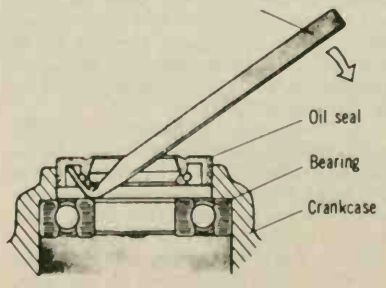


5. Bearings, either crankshaft or transmission, can be removed from the crankcases after taking away any oil seals, bearing retainer plates, or snap-rings which may be fitted.

6. Bearing removal may be facilitated by gently heating the crankcase with a propane torch in the vicinity of the bearing boss. Drive out the old bearing, refit the retainer, and drive the new one straight in with a bearing driver or a sturdy block of wood.

NOTE: *Install bearings and oil seals with the manufacturer's marks or numbers facing outward (i.e., visible after installation).*

7. Oil seals on both the crank and transmission shafts should always be replaced as a matter of course. Seals can be removed by prying them out of the cases with a screwdriver using a block of wood as a leverage point, as shown, or can be removed with a hooked tool. Some seals are fitted with snap-rings which must be removed first. Once removed, seals cannot be reused for any reason.



8. Install seals by pressing them straight into place with a large block of wood or the like. Ensure that the seal is not cocked in the case.

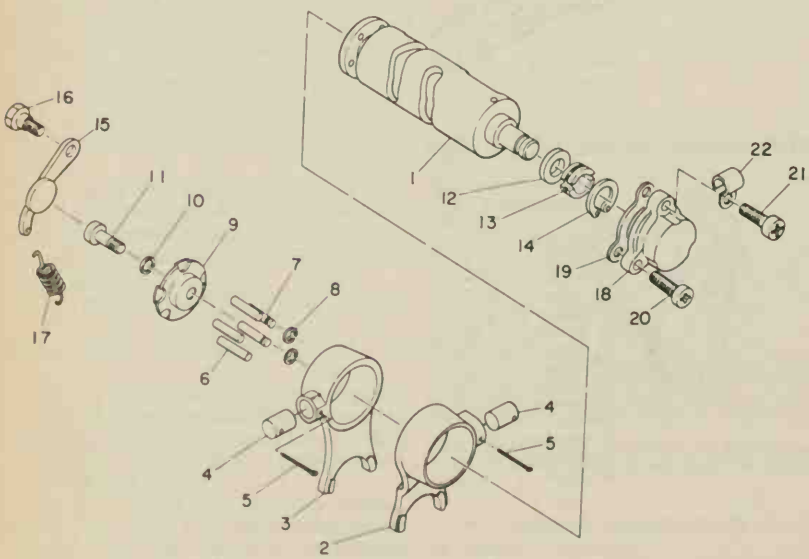
The seals must be correctly seated in the case as illustrated

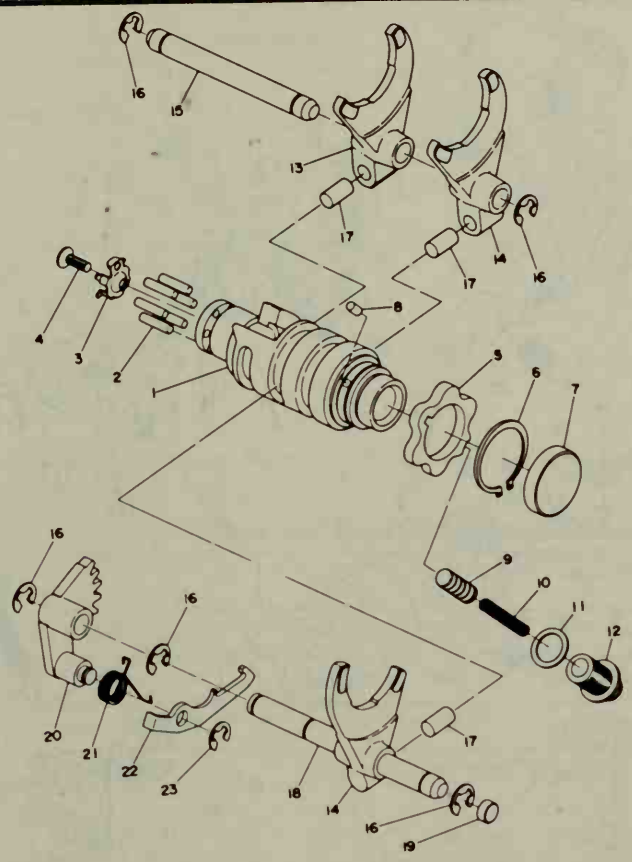
Models using snap-ring bearing retainers must have the gap in the snap-ring located at the mark on the crankcase (Courtesy Yamaha Int. Corp.)



The lips of the oil seals may become twisted when their shafts are inserted

9. Before assembling the cases, lubricate the bearings with the type of oil usually supplied to it (i.e., either transmission or two-stroke oil). Grease the lips of all oil seals before inserting any shafts into them.

10. Models which use large snap-rings to retain crank bearings may have an indicator mark on the crankcase. The open end of the snap-ring must be positioned at this mark as illustrated.



11. Bearing retainer plates (where fitted) must have their securing screws tightened firmly. Use an impact wrench or thread locking compound.

12. When assembling the cases, ensure that the shafts do not fold over the lips of their oil seals.

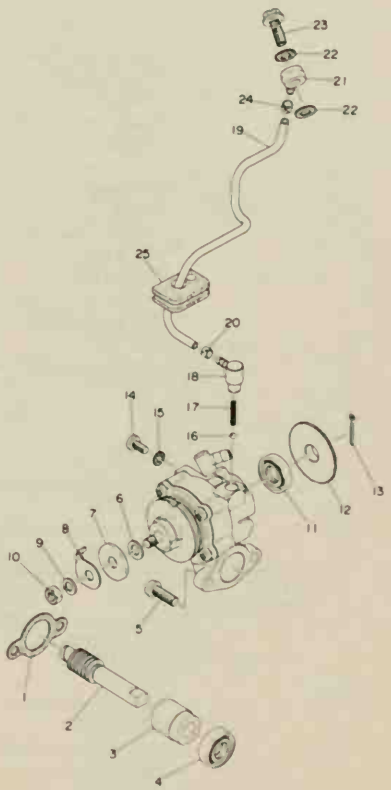
Lubrication System



The lubrication system is virtually maintenance-free except for checks on the oil pump cable adjustment, the minimum pump stroke setting (see the "Maintenance" section), and pump bleeding (necessary only if the Autolube tank has run dry, or if the oil lines are disconnected for any reason).

Oil Pump

The oil pump must never be disassembled for any reason. To do so will render the pump unserviceable. If lubrication problems are traced to the pump, it must be replaced with a new one.

REMOVAL AND INSTALLATION

1. Remove the oil pump cover.
2. Disconnect the pump cable from the adjusting pulley. Disconnect the oil tank-to-pump line and plug it to avoid oil loss.

3. Disconnect the pump-to-engine line. This may be either a simple hose fitting or a banjo fitting secured with a screw and sealed with gaskets on either side of the banjo.

CAUTION: *If oil pump inlet and outlet fittings are identical, mark the location of each hose before disconnecting it, so that the hook-ups will be correct when the pump is refitted. If banjo fittings are used for the outlet lines, take care that the gaskets are not misplaced.*

4. Remove the securing screws and remove the pump.

5. Cover the oil line ends with small plastic bags secured by rubber bands to prevent the entry of dirt or other foreign matter in the event that the pump will be out of the machine for some time.

6. Check the condition of all oil lines. Replace any that are cracked, torn, or which show signs of damage. Check the banjo gaskets for condition and replace them if cracked.

7. The oil pump mating surface may be fitted with either an O-ring or a gasket, and this item should be replaced each time the pump is removed.

8. Installation is the reverse of the disassembly procedure. Ensure that all hose fittings are correct. Do not overtighten banjo connection screws.

9. After installation, turn the throttle twist-grip from closed to full open. Note that the guide pin should not touch the adjustment pulley at any point in its travel.

10. Before starting the engine, bleed the pump (see below), adjust the pump cable and minimum stroke.

11. When replacing the oil pump cover, ensure that it does not pinch any oil lines.

BLEEDING

As noted above, bleeding the pump is necessary any time that the oil pump has been removed from the machine, whenever any of the oil lines has been disconnected, or if the Autolube tank has been drained or run dry.

Before beginning, ensure that the oil tank has a sufficient supply of oil.

1. Remove the oil pump cover. Place a suitable receptacle beneath the oil pump compartment to catch the drained oil.

2. The pump is equipped with a plastic starter plate on one end. This is used to bleed the system.

Oil pump bleed screw (arrow) (Courtesy Yamaha Int. Corp.)

3. Loosen and remove the bleeder screw on the pump body.

4. Open the throttle fully and hold it open during the bleeding operation.

5. With your other hand, turn the starter plate in the direction of rotation indicated by the arrow on the plate.

6. Continue turning the starter plate while observing the flow of oil from the bleeder hole. When the oil is completely free of air bubbles, replace and tighten the bleeder screw. The system has now been bled.

7. After this operation has been completed, start the engine and allow it to idle for a few seconds while holding the oil pump open with the cable. This is only necessary on newly rebuilt engines to ensure sufficient lubrication during the first moments of operation. If the pump is held open too long, the plug may foul.

8. After bleeding, check the pump minimum stroke and the cable adjustment.

9. If the bleeding procedure does not work (i.e., air bubbles continue to come out of the bleeder hole), check for air leaks at the hose junctions. With the engine running, squirt some clean Autolube oil at the hose connections. If bubbles form, there is an air leak at that point.

PUMP OUTPUT CHECK

The delivery output of the oil pump should be measured on models for which an output is specified after all other possible causes of trouble have been eliminated (see "Troubleshooting," below).

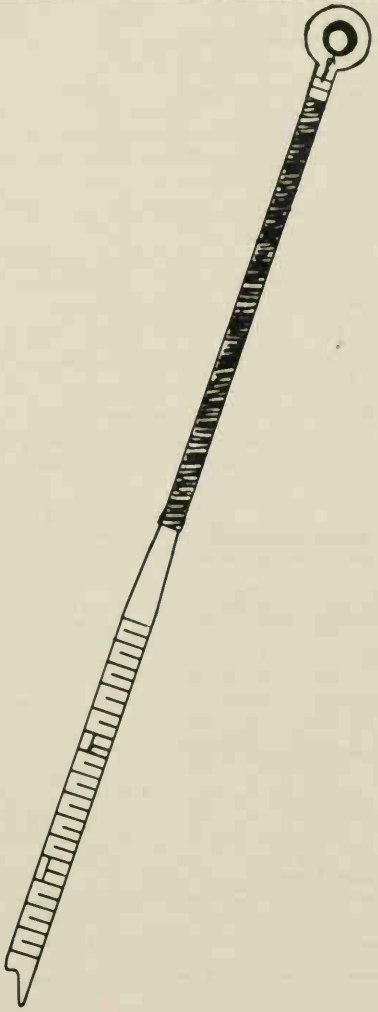
Needed for this operation are: a laboratory tube graduated in cubic centimeters, and an extra oil pump-to-engine delivery line.

NOTE: *This check can be performed with the pump mounted on the bike or on a bench.*

1. Cut one end off the extra delivery line and slide it over the end of the graduated tube (see the illustration).

2. Disconnect the oil pump delivery line banjo bolt and connect the extra one in its place with the graduated tube attached.

3. Make sure that there is sufficient oil in the oil tank, then set the pump at the minimum or maximum stroke.



NOTE: *When checking maximum output, turn the pump pulley so that the ramp moves along the guide pin to the maximum position. Do not push the pulley straight into position because the plunger stroke may then be longer than when in actual operation.*

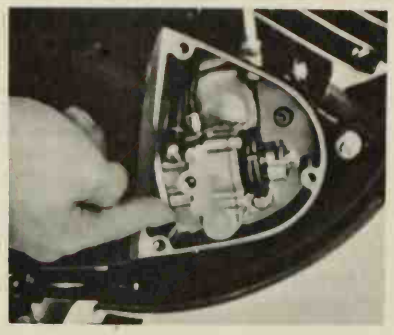
4. Turn the starter plate 200 revolutions in the direction of rotation indicated by the arrow on the plate. Measure the amount of oil in the graduated tube, and compare this figure with the standard value given in the "Autolube Pump Output" chart.

5. To check at minimum pump stroke, reset the pulley to the minimum output position, and repeat the operation.

TROUBLESHOOTING

Before proceeding, first check that the oil tank has a sufficient supply of oil.

A graduated cylinder and pump feed line is used to check pump output manually (Courtesy Yamaha Int. Corp.)



1. In the event of piston seizure or overheating not caused by component failure or incorrect timing or carburetor settings, check the oil pump cable adjustment, the oil pump minimum stroke, the quality of oil being used (poor quality oil will cause this); check that the breather hole in the oil tank cap is open or that the oil tank breather tube (if fitted) is not blocked. Check for air in the lines by bleeding the pump. Check for air or oil leaks in the lines from the tank and to the engine.

2. In the case of excessive smoking or oil consumption, check the oil pump cable adjustment. Check for leakage at banjo fittings, and cracked or broken oil lines. Make sure that the oil is of good quality.

3. Check that the oil pump is feeding oil to the engine by removing a banjo fitting, turning the throttle twist-grip fully open, and turning the starter plate by hand in the direction of rotation indicated by the arrow on the starter plate. Oil should dribble out of the banjo bolt hole. If it does not, either the pump is not getting any oil because of an empty tank, blocked feed line, or blocked tank breather, or the pump is defective. The latter would be an extremely rare occurrence.

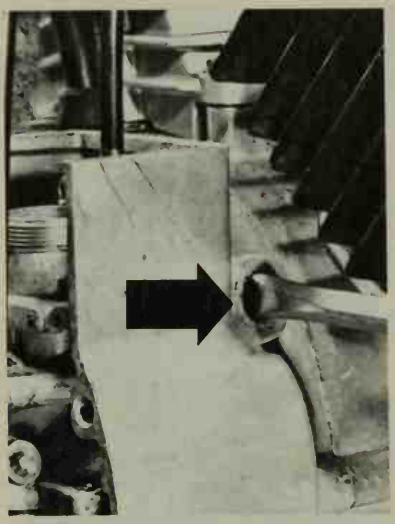
REMOVAL AND INSTALLATION

Rotary Valve Models

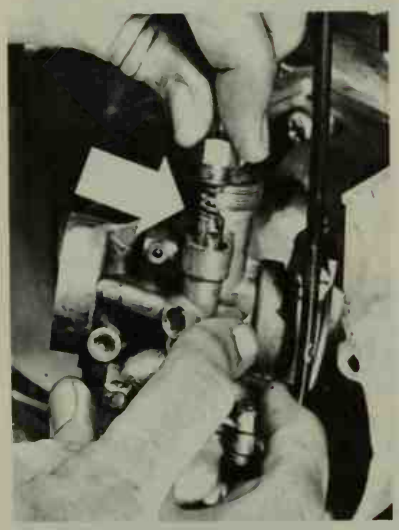
The carburetor is located beneath the cover at the forward end of the right-side engine case.

1. Lift up the rubber carburetor cover. Remove the rubber plug on the front of the right engine case. Using an impact driver, if necessary, unscrew and remove the carburetor cover.



2. Unscrew the carburetor cap and pull out the throttle slide assembly.

3. Shut the fuel petcock off. Disconnect the fuel line from the carburetor.



4. With a screwdriver (slot head) loosen the carburetor mounting clamp which is accessible through the plug hole at the front of the carburetor case.

5. Pull the carburetor off its spigot.

the float bowl. Unscrew the starter plunger and pull it out of the carburetor body.

7. Drain the gasoline out of the carburetor before disassembly.

8. Installation is the reverse of the removal procedure. Be sure that all lines are firmly attached and that the rubber grommets are properly seated.

Piston Port Models

1. Shut off the fuel petcock. Disconnect the fuel line at the carburetor.

2. Loosen the air cleaner clamp screw at the carburetor.

3. Disconnect the overflow tube from the float bowl and the breather tube from the carburetor body. Slip the breather tube out of the holder on the carburetor body.

4. Unscrew the carburetor cap and pull out the throttle slide assembly.

5. If the carburetor is bolted to the manifold, loosen each of the nuts ¼ turn at a time until loose, then remove them and pull off the carburetor.

6. If the carburetor is mounted on a rubber sleeve intake manifold, loosen the manifold clamp screw, and pull the carburetor off. Models with a locating slot-and-pin to align the carburetor must have the carb pulled straight off and not twisted or turned while removing.

7. Drain the gas out of the carburetor before disassembly.

8. Installation is the reverse of the removal procedure. If manifold gaskets are fitted, replace them if damaged or if condition is doubtful. On rigidly-mounted carburetors, tighten the mounting nuts evenly; do not overtighten.

DISASSEMBLY

All Models

Disassembly procedures will vary slightly depending on the type of carburetor fitted.

NOTE: *Note the location of all O-rings, washers, and gaskets when disassembling the carburetors. Refer to the exploded views if necessary.*

If disassembly of the throttle slide assembly is desired, refer to the procedures below. If a throttle stop rod is used to adjust the idle speed (rotary valve models), see Step 1 and following. On all other models, begin with Step 2.

1. The idle speed adjuster screw on the carburetor cap has a small cotter pin at the top. Removing this pin will allow the throttle stop rod to be taken out of the bottom of the throttle slide.

2. Compress the throttle slide against the carburetor cap until the end of the cable protrudes from the bottom of the

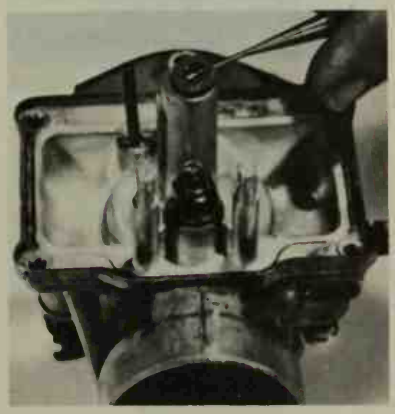
slide. Slip the cable end up along the slot in the slide until free, then remove the spring and the throttle slide.

3. Remove the spring seat or circlip from the inside of the slide, then turn it upside down to remove the needle and clip

NOTE: *Do not remove the needle clip unless its position is to be changed.*

4. Turn the carburetor upside down. On models with a float bowl-mounted main jet, remove the jet cover bolt and the jet. The main jet is unscrewed from the end of the bolt if replacement is desired. Remove the four float bowl screws, and remove the float bowl carefully.



NOTE: *If the carburetor is old or has never been disassembled, the float bowl may be stuck to the gasket. Use a plastic mallet to tap around the float bowl until it is free. Restraint should be exercised while doing this.*

5. On independent-float models, the floats will remain in the float bowl. If removal is desired, remove the clips which secure the floats to their shafts, and remove the floats. Push out the float arm lever pivot pin by hand or with a small punch and remove the float arm lever from the carburetor body.

6. On one-piece float assembly models, push out the float pivot pin by hand or with a small punch and remove

the float assembly.

CAUTION: *Carefully note or mark the top side of one-piece float assemblies, since damage could occur if the attempt were made to install the assembly in the incorrect manner.*

7. Remove the float needle. On some models, removal of the small needle retaining clip is required first.

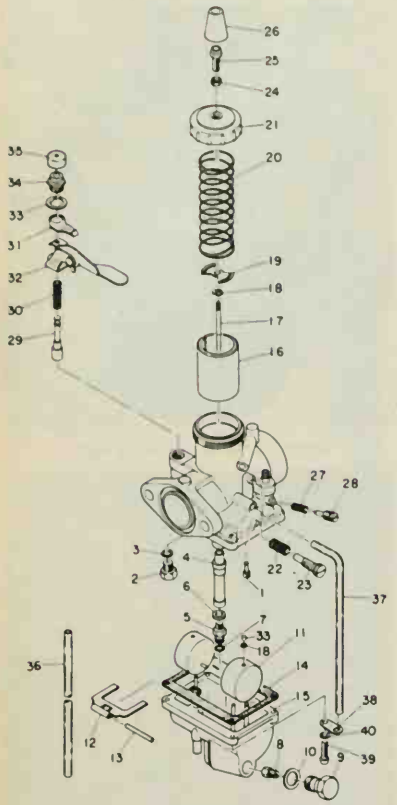
8. With a suitable socket, unscrew and remove the float needle seat.

9. Unscrew and remove the main jet on carburetors with a main jet mounted on the carburetor body.

10. On carburetors with a float bowl-mounted main jet, unscrew and remove the needle jet set bolt. The O-ring on this bolt *must* be replaced when the carburetor is assembled.

11. The needle jet is of two types, depending on model. If a hex-head is provided, simply unscrew and remove the needle jet in the same manner as the main jet.

If this is not the case, the needle jet is recessed into a holder in the carburetor body. After removing the main jet or set bolt, use a thin knife blade or something similar to remove the washer which is press-fitted at the bottom of the needle jet.



The needle jet is pressed into the carburetor body. To remove it, a wooden dowel should be used as a drift. Tap lightly on the needle jet to force the jet out of the carburetor.

12. Unscrew and remove the pilot jet.

13. If the starter plunger is still in place, unscrew the large nut on the carburetor body and remove the plunger assembly.

14. Unscrew and remove the pilot air jet. On most models, this is located on the side of the carburetor, but on some rotary valve models it is threaded into a passage just below the carb air intake.

15. Unscrew and remove the throttle stop screw (except rotary valve models). Both the pilot air screw and throttle stop screws are held in adjustment by small springs. Be careful that these are not lost when the screws are removed.

ASSEMBLY

1. The following parts should be replaced each time the carburetor is disassembled:

a. Manifold gasket and manifold O-ring (if fitted);

b. Float bowl gasket;

c. Float needle seat gasket;

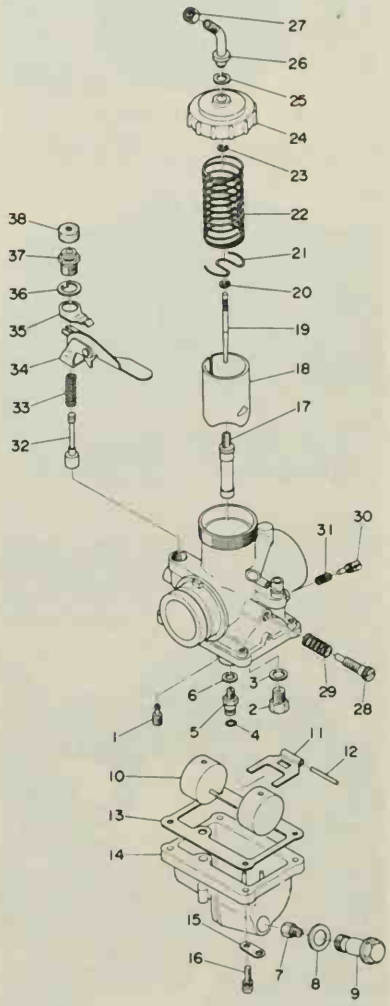
d. Throttle stop rod cotter pin (if fitted);

e. Needle jet set bolt O-ring (if fitted);

f. Main jet gasket (if fitted).

2. On rotary valve models, assemble the throttle slide assembly by first fitting the carburetor cap onto the throttle cable. Install the throttle stop rod through the bottom of the slide and attach it with the cotter pin to the top of the idle adjusting screw on the carburetor cap.

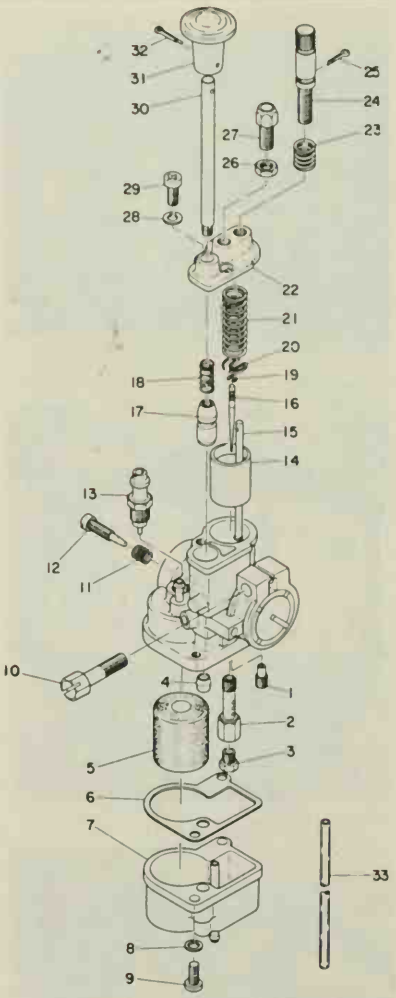
3. Install the needle, making sure that the needle clip is positioned in the same groove as it was found, unless tuning changes have been made.



4. Install the spring seat, return spring, and engage the throttle cable on the slide in the reverse of the disassembly procedure.

5. Install the pilot jet, being careful when screwing the jet in that it is properly seated.

6. Install the needle jet. If the needle jet is the pressed-in type, install it as it was removed with a wooden dowel drift, tapping it into its seat. Install the needle jet washer.



NOTE: *If this type of needle jet is used, make sure that it is installed with the cutaway at the top of the needle jet facing the ENGINE side of the carburetor.*

7. On models with a carburetor-mounted main jet, install the jet; tighten it securely. On models with the main jet in the float bowl, ensure that the jet is secured in the cover bolt, then install the cover bolt in the float bowl. Fit the needle jet set bolt on the carburetor body. A new O-ring should be used on the set bolt.

Installing the needle jet. The cut-away faces the engine side of the carburetor

Needle jet installation: the primary choke faces the intake side of the carburetor

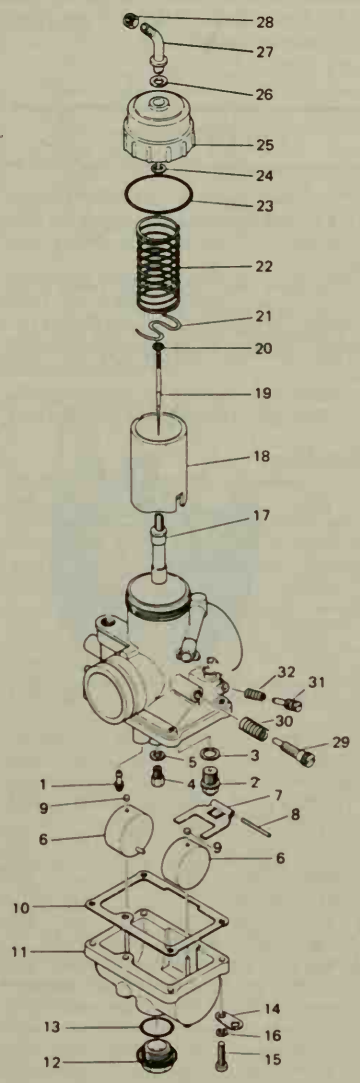
NOTE: *This O-ring MUST be in good condition if the carburetor is to function properly.*

8. Install the float needle seat gasket on the needle seat, and screw the needle seat into the carburetor. Insert the float needle into its seat.

9. On models with a one-piece float assembly, position the float assembly over the needle, ensuring that the correct side faces up. Slip the float pivot pin into the holder.

On models with independent floats, install each float into the float bowl, being sure that the pins on each float are positioned toward the bottom of the float bowl, and that they face *inward*. Secure the floats with the clips. Install the float arm on the carburetor.

10. Adjust the float level if necessary. See "Tune-Up."



11. Fit a new float bowl gasket. Install the float bowl, and install the four phillips head screws, tightening them gradually, and in an "X" pattern.

12. Refit the pilot air screw and spring. Screw in the pilot air screw until lightly seated, then back it off the prescribed number of turns given in the "Carburetor Specifications" chart at the end of this section. This is an approximate setting and may have to be readjusted when the engine is started. Install the throttle stop screw and spring.

13. Install the starter plunger in the carburetor body and secure it.

14. Install the carburetor on the manifold and install the throttle slide assembly.

15. Refer to the "Maintenance" and "Tune-Up" sections if necessary to adjust pilot air and throttle stop screws and throttle cables.

REED VALVE

The valve must not be handled excessively. Salt from the hands may damage the valve. Do not expose it to the sun and store it in a cool dry place if it is removed.

Removal

1. Remove the carburetor.

2. Remove the four valve securing bolts.

3. Gently remove the valve assembly from the cylinder. Do not pry the valve off.

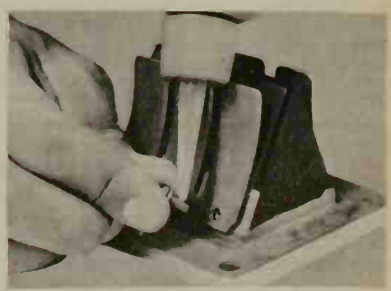
Removing the reed valve (Courtesy Yamaha Int. Corp.)

Inspection

1. If the reeds and the stopper plate must be removed from the case use the cut in the lower corner of the reed and stopper plate as a guide to reassembly.

2. Reinstall the reeds and stopper plates in their original locations.

3. Check the rubber parts of valve for cracking and other signs of deterioration.



4. Inspect the reed petals for signs of fatigue cracks. The reeds should seat flush against their neoprene seats, or nearly so. Apply a suction to the carburetor side of the reed valve: the leakage should be very slight.

5. Clearance between the valve stopper and the seat should be about 9 mm (0.35 in.).

1. Apply Lock-Tite® or some similar thread bonder to the reed securing screws so that they will not fall into the

engine during operation. Torque the screws to 0.32 in. lbs.

2. Install the valve carefully into the cylinder and tighten the valve securing bolts in a cross pattern.

Fuel Petcock

1. The fuel petcock contains a wire mesh filter which should be removed and cleaned every 2,000 miles or every few months.

2. Unscrew the sediment bowl ring nut after shutting the fuel off.

3. Remove the filter from the petcock, and clean the bowl and the filter in a solvent.

4. Make sure that the petcock can fully shut off the gas. If leakage is noted when the petcock is in the "Off" position, the petcock should be replaced.

5. Check the condition of the sediment bowl gasket, and replace it if damaged.

6. Replace the filter and sediment bowl. Do not overtighten the bowl nut. After installation, turn on the petcock and check for leaks.

If water has been getting into the carburetor from the gas tank, some or most of it can be removed by disconnecting the fuel line at the carburetor or petcock, placing a suitable container underneath to catch the gasoline, and turning the petcock to the "Reserve" position. Letting the gasoline run out for several seconds in this manner should remove any water present around the petcock line inside the gas tank.

Electrical Systems

General Magneto/ Alternator Service

Procedures for the removal and installation of the magneto flywheel and the individual magneto/alternator components are in the "Engine and Transmission" section. Removal of one or more of these components may be necessary to carry out some of the electrical system tests outlined below.

1. Examine the contact breaker points, if equipped, for pitted, burned, or worn contact surfaces. Dress the points with a small file or a wet stone, or replace them if necessary.

2. The contact breaker return spring tension should be about 24–32 oz on road/trail models, and about 35 oz on competition machines. Take careful note of the point rubbing block. The points should be replaced if the heel of the breaker assembly is excessively worn.

3. A test light or ohmmeter will be useful for testing circuit continuity and checking for current.

4. The areas of the magneto backing plate where the coil cores and other components are mounted should be cleaned with sandpaper to assure good electrical contact.

5. Be sure that the coil core ends are not contacting the inner (magnet) surfaces of the flywheel rotor. If they are, check the crankshaft for up-and-down movement which would indicate worn crankshaft bearings.

6. Check the flywheel for cracks or fractures, and replace it if necessary.

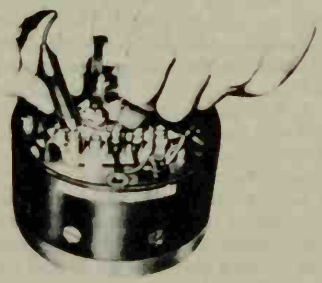
Checking for continuity between the commutator segments and the armature core (Courtesy Yamaha Int. Corp.)

1. Disconnect the white or red wire from the A (armature) terminal, and the green or black wire from the F (field) terminal.
2. Ground the F terminal to the E (black) terminal with a jumper wire.
3. Connect a voltmeter; positive voltmeter lead to the A terminal and the negative lead to ground.

Voltmeter connections for generator output test (Courtesy Yamaha Int. Corp.)



4. Start the engine, but do not rev the engine upon starting. *Slowly* speed the engine up to 2,000–2,500 rpm. Check the output on the voltmeter; 6-volt systems should produce 7.2–8.2 volts and 12-volt systems should put out 13.2–14.5 volts. If output is low, the generator must be checked. See Step 5 for further diagnostic checks. If output is normal and the system still fails to charge, check for loose or frayed wiring, bad regulator, bad battery connections, or poor connections at connecting blocks. If output is too high, check the regulator.
5. Check all brush wire connections. Check brush length. The limit line is marked. Replace brushes worn to the limit line. Make sure that the positive carbon brush is properly insulated.

NOTE: *Disconnect the negative brush before checking for a positive brush shorting.*

a. Check for any dirt, oil, or contamination;

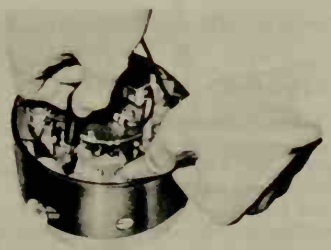
b. Check for proper continuity between the armature and field windings, terminals M, A, and F. If there is no continuity (an ohmmeter will read infinity), the coil is broken;

NOTE: *Lift the carbon brushes off the commutator before checking field winding resistance.*

Checking field coils for continuity (Courtesy Yamaha Int. Corp.)

c. Check field winding insulation with an ohmmeter set at the highest scale. Readings between the yoke housing and terminal "A" and the yoke housing and terminal "F" should be infinite (3 megohms or more).

6. If the preceding tests didn't reveal the problem, perform the following checks on the armature:



a. Make sure that the mica gaps are free from any carbon dust that could short out the individual bars;

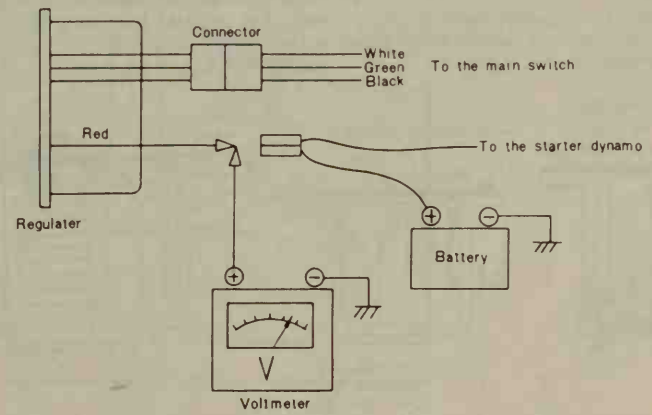
b. Make sure that the commutator surface is clean. If necessary, clean it up with a piece of fine emery cloth. Remember to remove the dust;

c. Check for continuity between the commutator segments and armature core. The readings should be infinite. There must be a completely open circuit;

d. Make sure that continuity exists between all the commutator segments;

e. If the insulation and continuity are good, the armature may be short-circuited and must be checked on a growler.

Checking positive brush insulation (Courtesy Yamaha Int. Corp.)

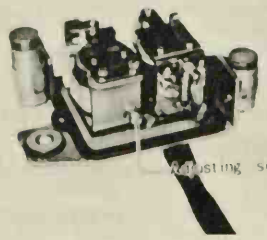


Starter Generator Brushes and Coil

1. Disconnect the negative starter brush and check the positive brush for insulation.
2. Disconnect the voltage regulator wiring and lift the positive brushes off the commutator. Make sure that there is continuity between terminals "A" and "M." No reading indicates a broken starter winding.
3. Disconnect the heavy motor winding wire from the positive brush and make sure that the windings are insulated.
4. With the heavy motor winding wire still disconnected from the positive brush, make sure that there is an open circuit between the "M" terminal and ground (at least 3 megohms).

Voltage Regulator Relay Test

NOTE: *If isolating a problem source, first check the generator as previously described, then check this relay.*



1. Check for any loose connections, broken solder, dirty points, etc.
2. Connect the correct voltage battery to the regulator coil as shown in the illustration, then insert a flat piece of steel into the electromagnetic field. If the steel is attracted by the field, the coil is OK.
3. Check the shunt resistors by connecting an ohmmeter positive lead to the "A" terminal and the negative lead to the "F" terminal. Manually operate the relay—each of the shunt positions should show a different resistance. If any of the positions indicate infinite resistance, one of the shunts is open.

Voltmeter connections for voltage regulator tests (Courtesy Yamaha Int. Corp.)

4. Check the yoke, core, and point gap with specifications. Adjust if necessary.

5. Check the regulator no-load voltage by starting the engine, disconnecting the wire at regulator terminal "B," connecting the positive lead of a voltmeter to the terminal and the negative lead to ground. Increase engine speed to the specified rpm and check the reading against specifications. The voltage can be adjusted by bending the spring hook or turning the

Voltage regulator adjusting screw (Courtesy Yamaha Int. Corp.)

adjusting screw so that the point pressure is increased or decreased.

NOTE: *Increasing the pressure raises the voltage.*

Voltage Cut-Out Relay

NOTE: *Check the cut-out relay if the generator and voltage regulator relay are in good condition.*

1. Check the relay magnetic field as previously described.

2. Check and adjust yoke, core, and point gap as previously described.

3. Check the relay cut-out voltage in the same manner as the voltage regulator relay. If necessary, bend the point spring hook so that the cut-out voltage meets specifications.

MAGNETO AND CDI MODELS

Magneto Assembly

1. Make sure that all connections are tight.

2. Check all parts for any oil or water spots.

3. The flywheel magnets eventually weaken. If the points and condenser are good, but lighting and spark are weak, replace the flywheel or have the magnets recharged.

4. Check the ignition and lighting coils for any signs of having burnt out, i.e., no continuity.

5. Make sure that the lighting coil wires all have continuity with each other.

Alternator Output

NOTE: *"Alternator" refers to the magneto/CDI charging coil.*

1. Connect the negative lead of an ohmmeter to ground and the positive lead to the yellow, green or green/yellow, and green/red wires from the magneto in turn.

2. Turn the key to the daytime riding position and start the engine

CAUTION: *Never run an alternator equipped model with the battery disconnected. Never disconnect the battery when the engine is running.*

3. Run the engine at 2,000 rpm and note the voltage reading. On 6V models, the reading should be 7.0–8.0 volts. On 12V models, the reading should be 13–14 volts.

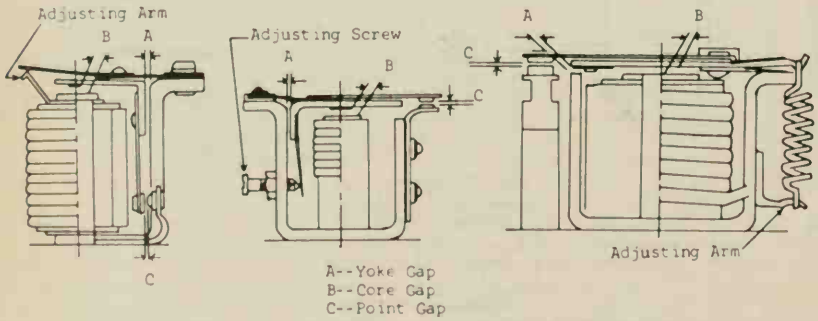
4. Run the engine to 7,000–8,000 rpm and note the voltage readings. 6V models should read about 8 volts. 12V models should read about 14 volts.

5. If readings are low, continue with component tests. If the components test OK, it is possible to increase the charging rate (except on some 1973 and all later models) by disconnecting the magneto green wire from its wiring harness connection, and reconnecting the previously unused magneto white wire to the green wiring harness wire.

Alternator Average Amperage Check

1. Disconnect the rectifier red wire.

2. Connect a DC ammeter positive lead to the red wire and connect the ammeter negative lead to the red wire connector.



3. Output at 3,000 rpm should be 2.8 ± 0.5A—day position; 1.5 ± 0.5A—night position. At 5,000 rpm, 3.2 ± 0.5A—day position, and 1.3 ± 0.5A—night position.

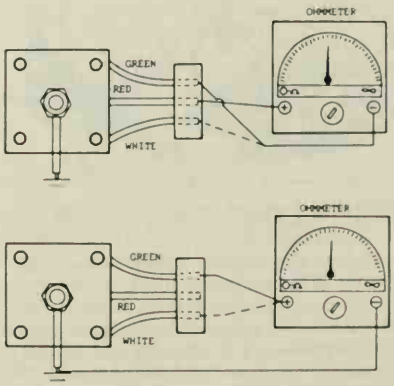
Charging Coil Resistance Check

1. Connect the negative lead of an ohmmeter to ground and the positive lead to the yellow, green, and green/red wires from the magneto in turn.

2. Read the resistance of the coil windings. The ohmmeter selector switch should be set to the low scale.

3. Resistance will vary according to model, but will generally be less than one ohm. Infinite resistance indicates a broken wire, while no resistance may mean a short.

Cutout relay adjustments (Courtesy Yamaha Int. Corp.)

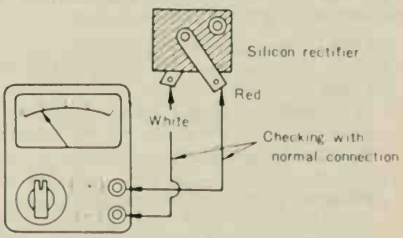


Rectifier

CAUTION: *The silicon rectifier can be ruined if it is subjected to overcharging or reverse battery polarity. Never reverse the battery connections and be careful not to inadvertently short the battery. Do not connect the rectifier directly to the battery to make a continuity check.*

Silicon Diode Rectifier (3-Wire) Continuity Check

1. Connect the positive lead of an ohmmeter to the red rectifier lead. Connect the negative lead to the green and then the white rectifier leads. The ohmmeter should show continuity (about 10 ohms resistance). Reverse the meter leads and there should be no continuity (several hundred ohms resistance).



2. Repeat the above with the ohmmeter connected to ground and the green, then the white rectifier leads.

Selenium Rectifier (2-Wire) Continuity Check

Connect an ohmmeter to the rectifier wire leads, then reverse the meter leads. There should be continuity one way, but not the other. Continuity in both directions or neither signifies a bad rectifier.

Ignition Coil

1. On battery-ignition machines, check primary winding resistance between the two primary terminals. It should be about 4 ohms.

On magneto-ignition models, primary winding resistance is checked between the primary wire and the coil bracket. Resistance should be 0.6 ohms for the 250 models, and about 1 ohm for other bikes.

2. On battery-ignition machines, check secondary winding resistance between one of the primary terminals and the spark plug lead. It should be about 10K ohms.

Other magneto-ignition machines, check secondary winding resistance between the spark plug lead and the coil bracket. It should be about 6K ohms.

1. Ohmmeter
2. Primary coil resistance value
3. Secondary coil resistance value
4. Ground
5. Primary lead wire
6. Ignition coil

3. Scrape some paint off the coil housing and check continuity between the primary winding and the coil housing. Resistance should read infinity. If it is not infinity, the coil windings are shorted.

4. Remove the plug cap and position the bare high-tension wire about ¼ in. from the cylinder head. Kick the engine over and check for a strong bright spark.

Condenser

1. Capacitance should be 0.30 mF.

2. After disconnecting the condenser lead, check resistance between the lead and the condenser casing using the highest available scale on the ohmmeter. Resistance must be infinite (more than 3 megohms).

Electric Starter Relay

If the starter motor does not function check the following:

1. Check for proper continuity in the starter relay core windings.

2. Check relay points for cleanliness.

3. When the points are closed, make sure that there is continuity between the battery and motor windings.

NOTE: *The starter relay is located either on the frame, as a separate unit, or within the voltage regulator housing.*

Pulser Coil (CDI Ignition)

The resistance between the white, red/white, and green pulser leads and ground is 90 ohms.

CDI Unit

The CDI unit or black box cannot be tested without the use of a special testing unit designed for the purpose. Do not attempt to disassemble the CDI unit. There are no serviceable parts in the unit. Do not subject the CDI unit to shock. If either the CDI unit or the ignition coil are relocated, place them in a dry, well-ventilated location on the machine.

Wheels and Brakes

FRONT WHEEL REMOVAL AND INSTALLATION

Procedure will vary according to the type of forks fitted.

1. Support the front wheel several inches off the ground by placing a crate or the like beneath the motorcycle if necessary.

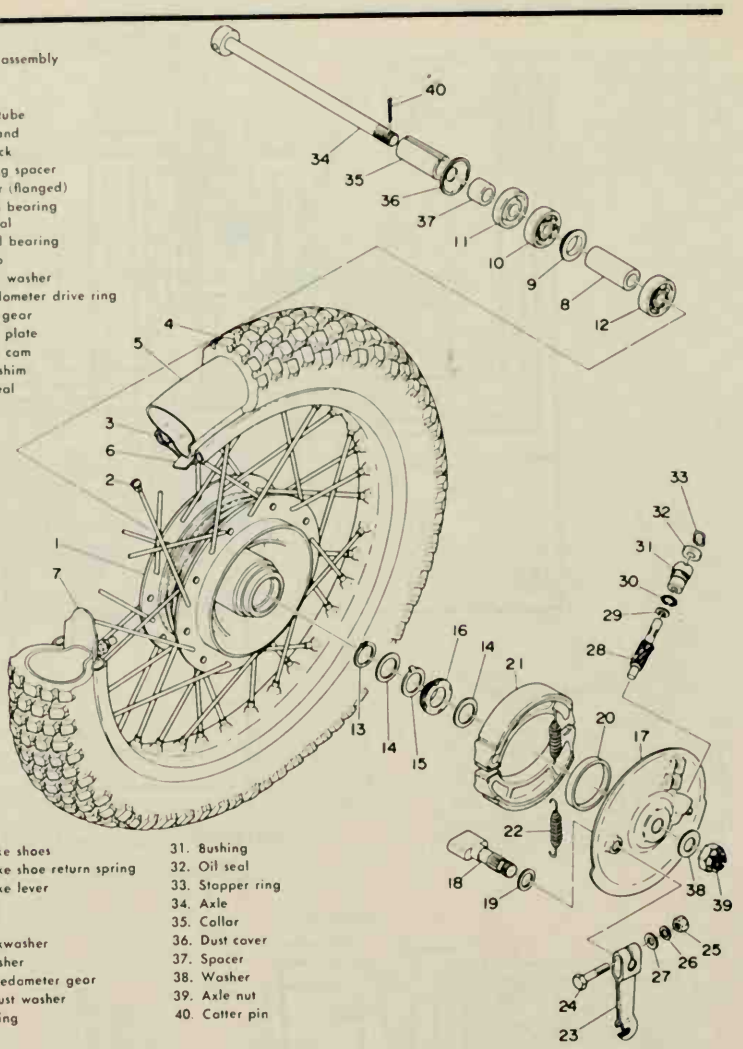
2. Disconnect the brake cable from the handlebar lever, and then from the lever on the brake plate. Detach the cable from the adjuster if the adjuster is equipped with a slot for this purpose. If not, unscrew the adjuster from the brake plate.

3. Remove the bolt or screw which secures the speedometer cable, and pull the cable out of the hub, ensuring that the rubber O-ring on the end of the cable is not damaged as this is done.

4. The front wheel is secured in a number of ways depending on model. On most lightweights, the axle is held only by the axle nut. On others, a pinch-bolt is fitted to one fork slider. On larger models, an axle cap (secured by two small nuts) is used.

5. Remove the axle nut cotter pin if fitted. Then remove the axle nut. Loosen the slider pinch-bolt (if so equipped), and/or remove the axle capnuts and the axle cap.

6. Insert a phillips head screwdriver or similar tool into the axle and pull it with a twisting motion out of the sliders.



7. Remove the wheel from the forks. On some lightweight models, an axle spacer on the left-side of the hub protrudes about an inch out of the oil seal. This spacer should be oiled lightly and then taken out of the seal using a twisting motion. If a dust cover is fitted to the hub, remove it now to avoid loss during handling of the wheel.

8. Refer to the wheel component service sections below if necessary. Installation is the reverse of the removal procedure. Ensure that the brake anchor cast into the brake plate is engaged with the slot on the fork slider. Tighten the axle nut securely. Refer to the "Chassis Torque Specifications" chart at the end of this section. Using a new axle nut cotter pin is recommended.

After tightening the axle nut, secure the pinch-bolt or axle capnuts. Tighten the capnuts evenly so there are even gaps on both sides of the axle.

REAR WHEEL REMOVAL AND INSTALLATION

Two types of rear wheel assembly are fitted. On most models the sprocket and the rear wheel are removed together. On some models, the sprocket hub assembly is separate and can remain in place on the swing arm when the rear wheel is removed. This latter type is fitted to such machines as the LT2, DT100, and HT1, and is identifiable since a large sprocket nut is fitted which secures the sprocket assembly to the swing arm.

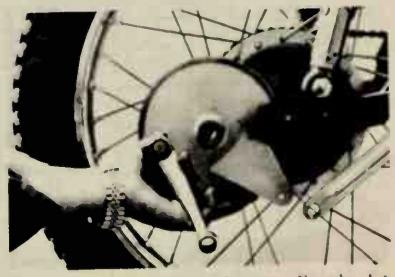
1. On machines with sprockets bolted to the wheel, disconnect the drive chain.

2. Remove the brake anchor cotter pin. Remove the brake anchor nut and bolt and detach the anchor from the brake plate.



3. Unscrew and remove the brake rod adjuster nut. Depress the brake lever and disconnect the brake rod from the brake plate lever. Remove the spring and place it along with the adjuster nut and clevis pin fitting in a safe place.

4. Loosen the nut on each chain adjuster. Back off the chain adjuster bolts or nuts to allow some free-play in the rear wheel.

5. Remove the rear axle nut cotter pin, the rear axle nut, and tap out the axle using a plastic mallet or pull it out with a twisting motion.

6. After the axle is removed, remove the axle spacer on the right-side of the wheel, and the right-side chain adjuster. Pull off the brake plate and remove it from the machine. Pull the wheel as far as possible to the right and remove it. On some models it may be necessary to lean the motorcycle to the left while removing the wheel.

7. Installation is the reverse of the removal procedure. On models with separate sprockets, ensure that the driving tabs on the sprocket assembly are engaged with the slots in the hub's rubber dampers. On other models, install the chain masterlink spring clip facing the direction of chain rotation. Adjust chain tension and the rear brake in that order. Tighten the axle nut securely. Torque the axle nut to the values given in the "Chassis Torque Specifications" chart at the end of this section.

BRAKE SERVICE

Front and Rear Brakes

1. Brakes can be inspected in place

on the brake plate.

2. Inspect the linings for wear. There should be at least 0.03 in. (0.77 mm) of lining material left (measured at the lining's thinnest point) or the shoes must be replaced.

3. Inspect the linings for scoring or grooves.

Be sure that there is no oil or grease present on the linings. Oil-impregnated linings must be replaced.

4. If the linings are usable, rough up the surface with sandpaper. Then clean the linings thoroughly with alcohol or lacquer thinner. Clean the brake drum with the same solvent.

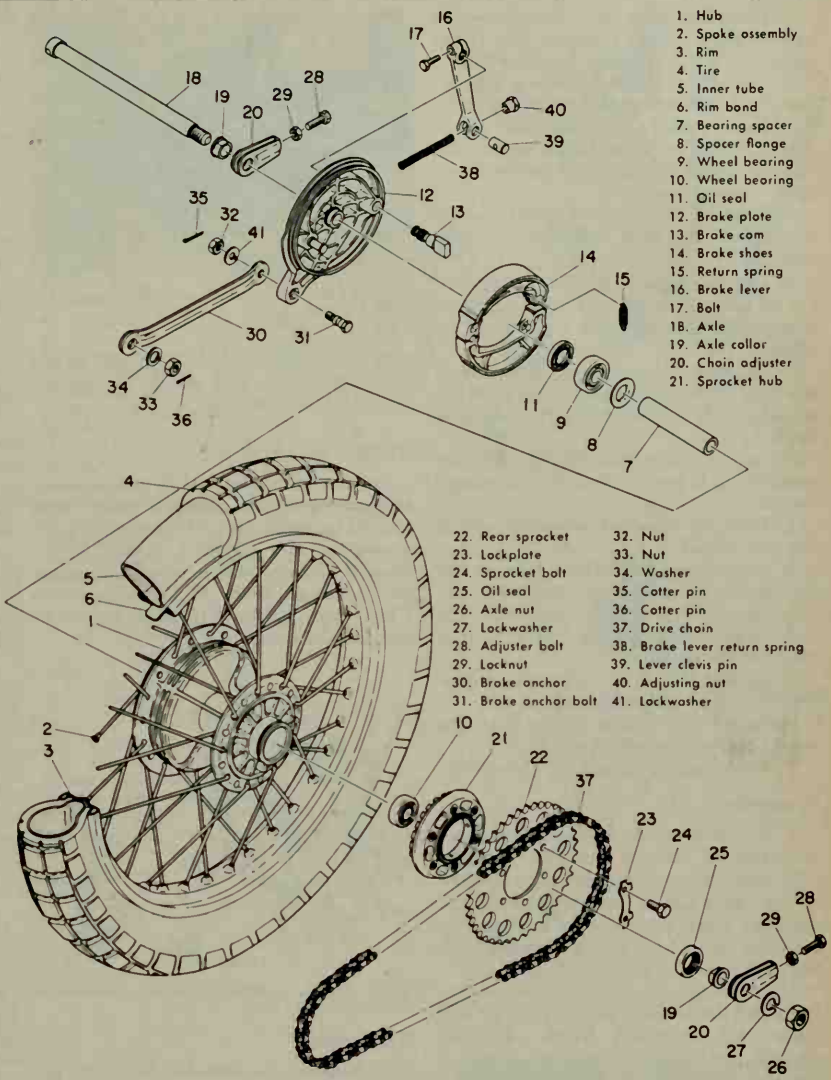
5. To disassemble the brake plate, simply grasp each shoe and fold them toward the center of the brake plate as shown. They may be installed using the same method.

6. Remove the brake springs. Remove the brake lever pinch-bolt and pull the lever off the splined brake camshaft.

7. Push the brake cam out of the plate from the outside using hand pressure or by tapping with a plastic mallet. Note the presence of any shims on the cam and be sure they are in place when the brake plate is ressembled. Remove the dust seal from the brake plate.

8. Check that the brake lever pinch-bolt is not bent. This can easily happen if it is overtightened. Replace any bolts in this condition. Inspect the brake lever splines and replace the lever if these are worn or torn.

Removing the brake shoes from the brake plate



9. Inspect the splines on the brake cam. These should be in good condition. Check that the brake cam is not bent and that it can rotate freely in the brake plate passage. If it will not, use a fine grade of sandpaper on the camshaft and the surface of the brake plate passage.

10. Clean the cam thoroughly in a solvent to remove any old grease, rust or corrosion. Use sandpaper or emery cloth to polish the cam. Clean off any residue; before reassembly, smear the cam with chassis grease.

11. Inspect the brake plate for cracks or fractures, and replace it if necessary.

12. Check the condition of the brake springs, noting any twisted or fatigued hooks. Replace any broken, rusted, or old springs with new ones.

13. Clean all parts thoroughly with a suitable solvent, making a special effort to remove the dust and built-up dirt from the brake plate.

Rear wheel assembly (Courtesy Yamaha Int. Corp.)

14. When reassembling the hub, note the following points:

a. Ensure that the brake cam is lubricated with chassis grease and that any shims which were on the cam are in place;

b. The use of new dust seals is recommended;

c. Lubricate the brake shoe pivot points with a little grease;

d. Install the shoes as on removal. Hook them together with the springs, and fold them down over the brake cam and pivot.

Brake Drums

1. Upon disassembly of the hub, inspect the brake drum surface for condition. The drums must be clean and free from score marks or rust.

2. Rust can be removed from the drum surface with sandpaper. Polish the surface until it is shiny, then clean it thoroughly.

3. Alcohol or lacquer thinner can be used to remove dirt or deposits from the drum.

4. The drum should be checked for concentricity. An out-of-round condition is usually noticeable as an on-off-on feeling when the brake is applied while riding. With the wheel assembly mounted on the machine, spin the wheel while applying the brake very lightly. The rubbing noise of the brakes against the drum should be heard for the entire revolution of the wheel.

5. An out-of-round condition and most scoring can be removed by having the drum turned on a lathe.

SPROCKET ASSEMBLY

The rear sprocket assembly consists of the sprocket, sprocket hub, bearing, and rubber dampers.

Removal and Disassembly

On models with the type of sprocket assembly which remains on the swing arm when the wheel is removed, proceed as follows:

1. Disconnect the drive chain. Unscrew the large sprocket hub nut and remove the assembly from the swing arm.

2. Bend down the tabs on the sprocket bolt locking plates. Unscrew the bolts, and remove the sprocket from the hub.

3. To remove the hub bearing, first remove the sprocket shaft by tapping it out from the sprocket side of the hub. Use a plastic mallet or wood block so that the sprocket shaft threads will not be damaged when struck.

4. Take off the sprocket shaft collar by hand, then the dust seal (fitted to late models).

5. Use an elbow-shaped tool to pry out the oil seal. If the oil seal is damaged on removal, as is likely, a new one must be fitted.

6. Remove the circlip on the inside of the hub. Drive the bearing out toward the sprocket side of the hub with a suitable drift.

On models in which the sprocket assembly and rear wheel are removed together:

1. Pull the sprocket assembly out of the rear wheel.

2. Bend down the locking tabs on the sprocket bolts and remove the bolts.

3. Remove the sprocket from the hub.

4. Remove the sprocket hub dust seal. Pull out the collar.

5. Pry out the oil seal out with a screwdriver or elbow-shaped tool.

6. Remove the large circlip from the wheel side of the sprocket hub.

7. Drive out the sprocket hub bearing.

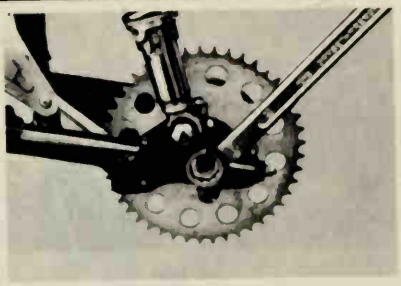
Inspection

1. For bearing inspection and lubrication, refer to "Wheel Bearings," below.

2. Check the condition of the sprocket. If the sprocket is warped, or if the sprocket teeth are worn or hooked, the sprocket should be replaced along with the chain and the engine sprocket.

3. Check the condition of the sprocket bolts and the locking plates. Replace any bolts with rounded heads, stripped threads, or those which are bent or cracked. Bolts must be tightened securely upon installation. It is also recommended that they be secured with a thread locking compound. The locking plates must not have fatigued or cracked edges, since these are used to lock the bolts in place. Replace the plates if damaged in any way.

4. Check the condition of the oil seal and replace it if the lips are damaged.



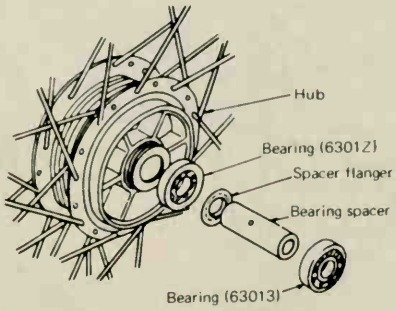
5. Inspect the sprocket shaft for broken or stripped threads.

6. Check the condition of the rubber dampers in the wheel hub. These take up any driveline shocks when the clutch is released and have an important effect on chain and sprocket life. Replace any damper which is crushed or damaged. In instances where the damper is a tight fit in the hub, some engine oil or dishwashing liquid can be used to facilitate removal and installation.

Assembly

1. Assembly is the reverse of the disassembly procedure.

2. Lubricate the bearing as described in "Wheel Bearings," below. The bearing should be driven into place with a bearing driver or a suitable substitute.



Removing the sprocket hub assembly (Courtesy Yamaha Int. Corp.)

3. Grease the lips of the oil seal before installation. The seal should be pressed into the hub with care.

WHEEL BEARINGS

Removal of the wheel bearings necessitates removing the hub oil seals. These should be replaced with new ones upon reassembly. In addition, a drift with a hooked end should be used to remove the bearings. Refer to the illustration. Clean the outside of the hub before removing the bearings.

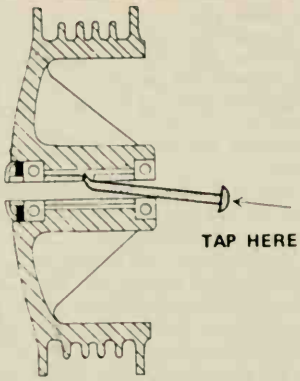
Wheel bearing assembly (Courtesy Yamaha Int. Corp.)

Disassembly

1. Remove the wheel and take out the brake plate.

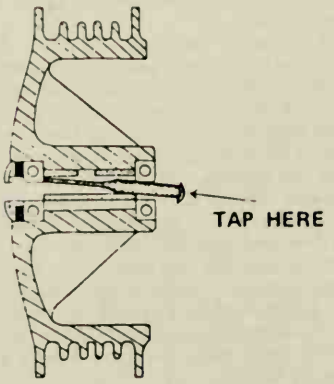
2. Remove the speedometer drive mechanism from the hub if fitted. Remove any dust covers, seals, or axle spacers fitted to either side of the hub.

3. Pry out the hub oil seals using a small screwdriver, or, preferably, an elbow-shaped tool.



4. Using the bearing removal tool, or a suitable substitute, engage the hole drilled into the bearing spacer. Striking the removal tool with a hammer will drive out one wheel bearing. Alternately, a straight punch may be used to remove the bearing. Move the spacer to one side as shown in the illustration and tap out the bearing.

5. Take out the bearing spacer and spacer flange. Drive out the other bearing.



NOTE: *On some models, especially high mileage machines, the hub should be heated gently with a propane torch in the vicinity of the bearing bosses to facilitate removal.*

Inspection

NOTE: *The following bearing inspection checks refer to the sprocket hub bearing as well as wheel bearings.*

Hooked tool used for removing wheel bearings (Courtesy Yamaha Int. Corp.)

A straight punch can also be used to remove the bearings (Courtesy Yamaha Int. Corp.)

1. Clean the bearings, washers and spacer tube in a suitable solvent, removing all of the old grease. At this point, it would be wise to clean out the hub as well.

2. Check the bearing bosses in the hub for scuffs, cracks, or distortion. If they are in any way damaged, the hub must be replaced.

3. Check the condition of the steel washers and the spacer and replace if damaged.

4. Apply a few drops of light oil to the bearing, and spin it. The bearing must rotate smoothly and freely. Any roughness or binding in rotation will necessitate a new bearing

5. Note that bearings must be replaced in pairs.

Assembly

1. Obtain a good grade of wheel bearing grease to lubricate the wheel bearings.

2. Pack the grease in the bearing.

3. Heat either side of the wheel hub with a propane torch as on removal of the bearings. Place one of the bearings in the hub, and make sure that it is seated. Use a bearing driver or a block of wood to install the bearing. Center the bearing in the bearing boss, then strike the drift sharply until the bearing is seated.

NOTE: *Bearing must be driven straight into the hub. Do not attempt to force in a cocked bearing.*

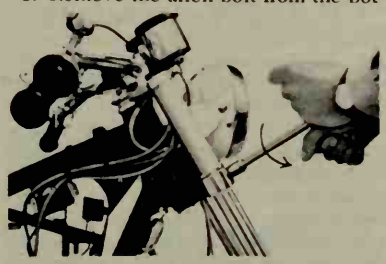
4. Fit the spacer flange and spacer, and install the other wheel bearing.

5. Press in new oil seals on both sides of the hub.

Front Forks

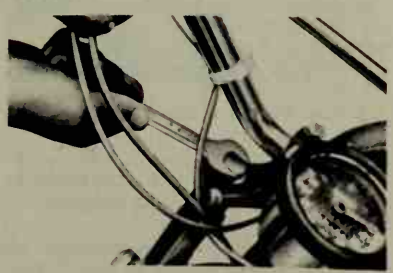
REMOVAL AND INSTALLATION

1. Remove the front wheel.
2. Remove the front fender.
3. Loosen the pinch-bolts on the lower triple clamp. If equipped, loosen the pinch-bolts on the upper triple clamp.
4. Remove the fork filler caps on models without upper triple clamp pinch bolts. Loosen them on other models.



NOTE: *It may be necessary to loosen and pivot the handlebars out of the way for clearance.*

5. Slip the tubes out of the triple clamps. On some models, the top of the fork tubes is tapered and may be stuck in the upper triple clamp. The tube may be broken loose by tapping the side of the upper triple clamp with a plastic mallet. Or, thread the cap bolt into the top of the fork tube about halfway and sharply rap the nut with a plastic mallet. Do not strike the nut hard enough to distort the nut or tube threads.
6. Assembly is the reverse of removal; however, start reassembly by sliding the tubes into the triple clamps and snug up the lower triple clamp pinch-bolts just enough to hold the fork leg. The tops of the fork tubes must be flush with the top surface of the upper triple clamp.
7. Tighten the lower triple clamp pinch-bolts and then the upper pinch bolts. Secure the filler caps.



DISASSEMBLY

Enduro-Type Forks

1. Remove the fork legs.
2. Remove fork filler caps, the fork spring(s) and spacers from the top of the fork tube. Drain the fork oil into a container.
3. Remove the allen bolt from the bottom of the fork slider. It may be necessary to use an impact driver on these bolts.

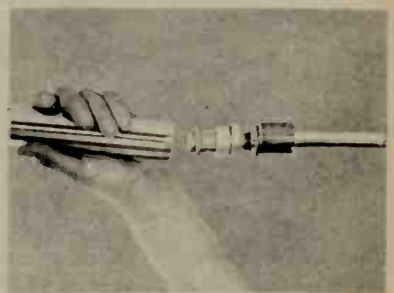
If the allen bolts turn, but do not come out, the damper inside is turning as well. Temporarily reinstall the fork spring(s) and filler cap which will usually serve to hold the damper so that the allen bolt can be broken free.

On models such as the DT100, a large circular nut is fitted to the top of the fork slider. Lift the dust cover off the slider, and unscrew and remove the slider nut as described in Steps 5 and 6 under "Standard Telescopic-Type Forks," following.



4. Pull the fork slider off the fork leg.
5. Remove the circlip from the bottom of the fork tube and take out the damper components.
6. Remove the dust cover from the top of the slider. Remove the snap-ring, dust seal and washer (if fitted). The oil seal is pried out of the slider with a small screwdriver as illustrated. Protect the slider lip with a cloth.
7. Remove the sliding bushing from the fork tube, if fitted.

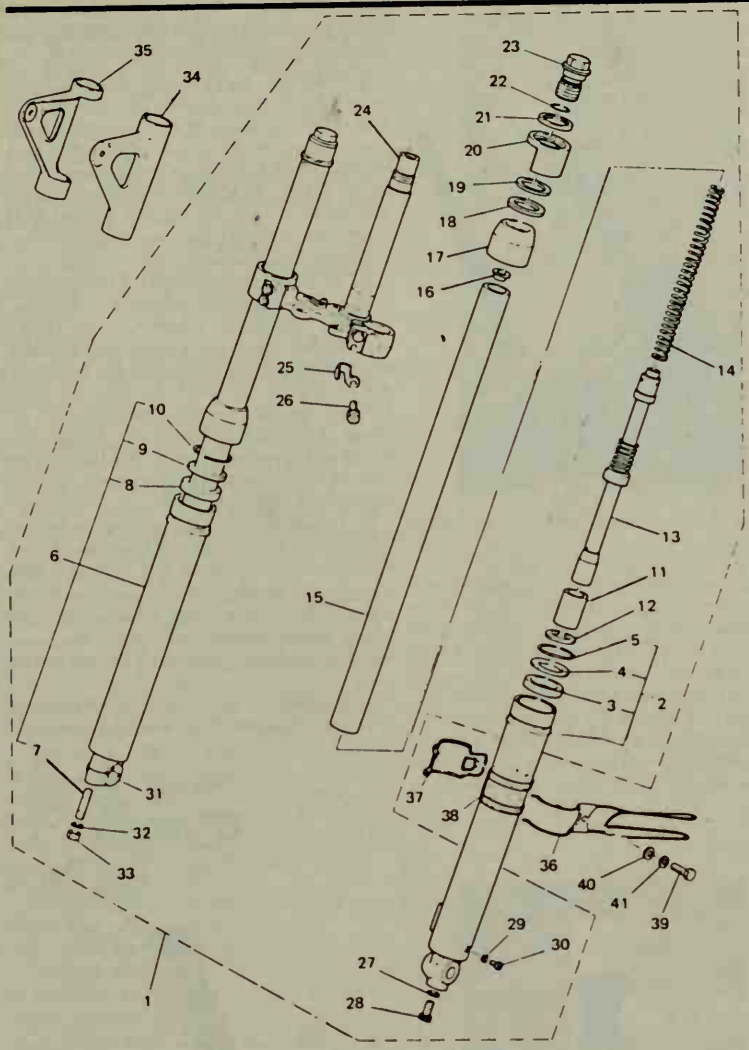
2. Remove the fork filler cap, washer, and O-ring.

3. Remove the fork boot (external spring forks), spring seats, and spring from the fork leg.

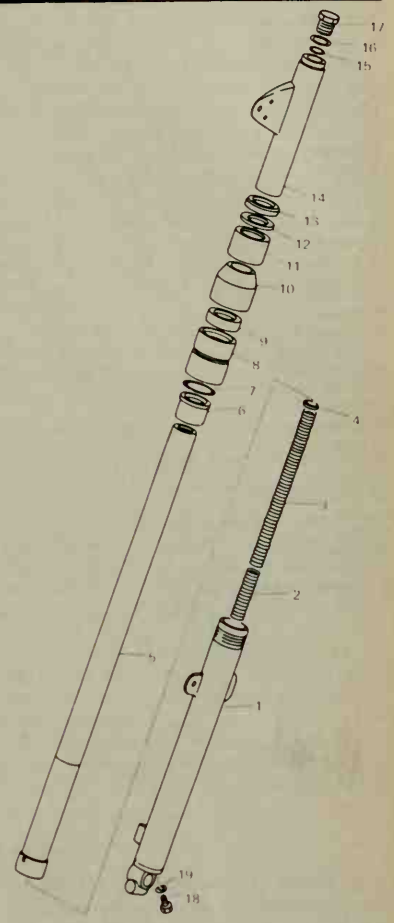
4. Drain the oil out of the top of the fork tube into a suitable container.



5. To disassemble the fork leg, a device must be used to clamp the slider nut so that it can be turned. In many cases, a large heater hose clamp will work. Tighten the heater hose clamp around the slider nut; a piece of old inner tube should be used beneath the clamp to protect the chrome. Clamp the slider in a vise, preferably by the axle lug. Unscrew the slider nut and remove the slider from the fork tube.

An alternative method requires clamping the slider nut in a vise (protected with rubber padding or the like), and unscrewing the slider from it as shown in the illustration.

A strap wrench on the slider nut, if one is available, is the easiest method.



6. Remove the slider nut with the oil seal by the top of the fork tube, followed by the O-ring (if fitted) and sliding bushing.

7. The oil seal, which must be replaced, can be pried out of the circular nut with a small screwdriver or hooked tool.

INSPECTION

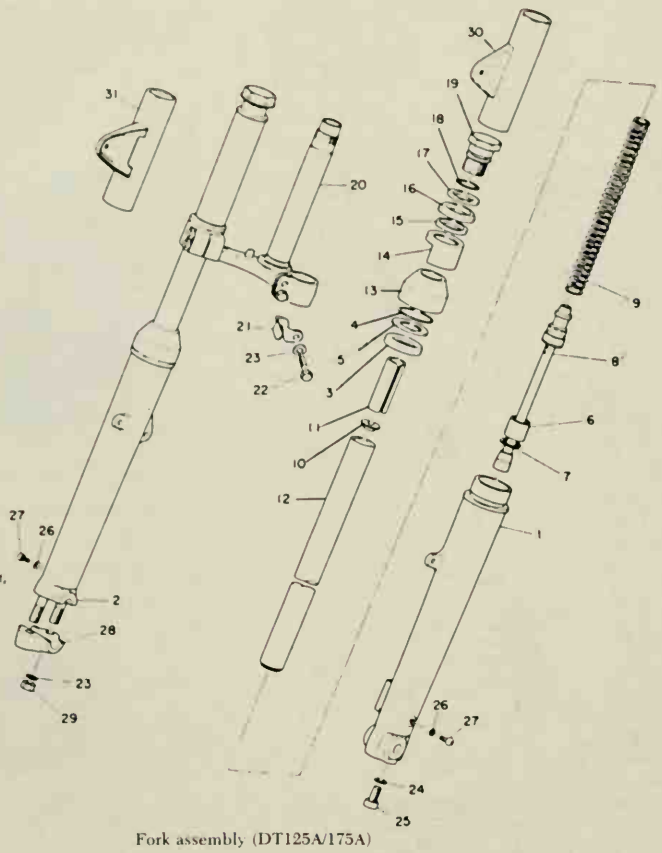
All Models

Inspection procedures are applicable to all types of forks, with allowances for the type of components fitted.

1. Clean all metal parts in a suitable solvent.

2. The fork tubes must be perfectly straight. If a set of V-blocks and a dial gauge are available, run-out should be checked. If a tube is bent more than 0.06 in. (1.5 mm) (true indicated reading), the tube should be replaced. If absolutely necessary, a tube which is bent but not kinked can be pressed to straighten it, but this is not recommended.

3. If chrome plated, the plating must be in good condition over the length of the fork tube. All rust and corrosion should be removed by some low-abrasive method.



4. That portion of the tubes on which the oil seals ride must be perfectly smooth and free of rust, corrosion, scoring, or scratches. If the area cannot be smoothed out, the tube should be replaced. Otherwise, the seals will leak.

5. Check the tops of the tubes for damaged threads. Inspect for worn or scuffed slider surfaces. Replace the tubes if wear is evident. The fork tube piston (at the bottom of the tube on standard telescopic forks) must be completely free of scoring or wear marks. If it is not, the tube must be replaced. On Enduro-type forks, the piston is a separate part. It should be checked for wear, however, and replaced unless it is in perfect condition.

6. Check the fork sliders for cracked, broken, or distorted axle brackets, worn inner bore surfaces, damaged threads, damaged fender mounts, or dents which have affected the inner bore. Replace the sliders if defective in any of the above ways.

7. On standard forks, inspect the sliding bushing for wear or scoring. Place the bushing on the fork tube. If it can be rocked back and forth, it is too worn for use and must be replaced with a new item.

Place the bushing in the fork slider. If it shows play here, it must be replaced.

Fork assembly (DT125A/175A)

8. Check the circular nut for distortion, damaged threads, or a damaged oil seal seat.

9. On Enduro-type forks, check the damper for any scoring or other damage. Replace if necessary.

10. Check the fork springs for cracks or other obvious damage. The two fork springs must be with ¼ in. of equal length, or both should be replaced.

Assembly and Installation

ALL MODELS

1. Assembly is the reverse of the disassembly procedure. Note the following points.

2. All O-rings, oil seals, and felt washers must be replaced.

3. Slider oil seals should be pressed directly into the slider or circular nut (depending on fork type) with a suitable drift, such as a large socket, which will cover the whole seal. This will minimize chances of distorting the seal when installing it and will allow it to be fully seated. The old oil seal can sometimes be used to drive in a new one.

4. Grease the lips of the oil seals before installing on the fork tubes. After installing the slider on the fork tube, check that it can move smoothly up and down.

5. When installing the tubes in the triple clamps, ensure that the top of the tubes are flush with the top surface of the upper triple clamp.

6. Refill each fork leg with the proper viscosity and quantity of oil.

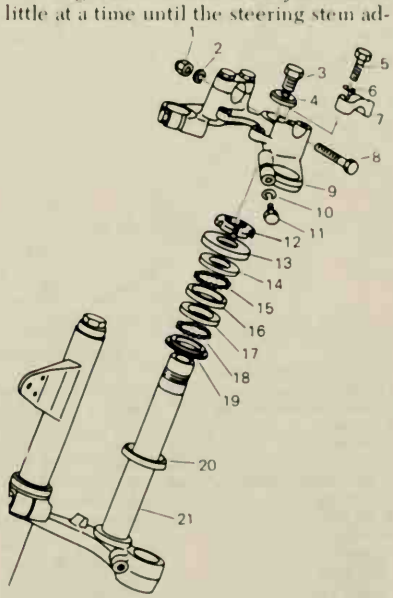
Steering Stem

BEARING ADJUSTMENT

1. The steering stem bearings are uncaged 3/16 in. or ¼ in. balls. They are adjusted by means of a ring nut beneath the upper triple clamp.

2. To check bearing adjustment, support the front wheel off the ground. Grasp the fork sliders.



3. Attempt to move the forks by pushing and pulling on the sliders. If play or movement can be felt the bearings are too loosely adjusted or worn.

4. Turn the forks slowly from lock-to-lock. Movement should be smooth, silent, and effortless. If any binding or uneven movement is felt, the balls and races are either too tightly adjusted or are worn. If the steering feels uniformly stiff, the bearings are too tightly adjusted. If any noise is noted, the bearings are damaged, or some are missing.

5. With the front wheel off the ground, release the front forks from a few degrees off the centered position. The forks should fall freely to either side of their own weight. If they will not, the bearings are too tightly adjusted, the steering stem is bent, the races are extremely worn, or some of the balls are missing. At the centered-fork position, check that there is no detent in the bearing movement. This is caused by damaged races.

6. Bearings on most models can be adjusted with a hammer and blunt punch on the adjuster nut with the upper triple clamp still in place. However, the triple clamp pinch-bolts, fork filler caps, and triple clamp crown nut should be loosened to allow movement of the adjusting nut.

7. Tighten or loosen the adjuster nut a little at a time until the steering stem ad-

justment conforms to that outlined above.

8. If proper adjustment is not possible, the bearings and races will probably need to be replaced.

REMOVAL

1. Disconnect the cables, remove the electrical switches from the handlebars; unbolt and remove the handlebars from the motorcycle.

2. Unbolt the instruments from the upper triple clamp and lay them carefully aside. Unbolt the headlight from the brackets and allow it to hang by the wiring harness.

3. Remove the front wheel, fender, and remove both fork legs from the triple clamps.

4. Loosen the steering stem pinch-bolt. Then remove the steering stem nut, the spring on models with a steering damper, and the large washer.

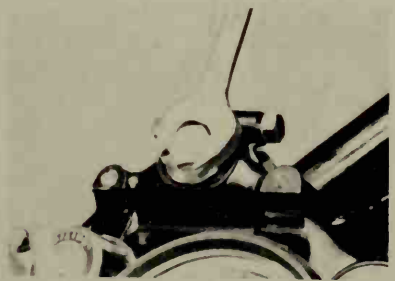
5. The upper triple clamp can now be removed. Tap upward on the underside of the triple clamp with a plastic mallet until it is free.

6. Remove the headlight brackets. Since the steering head ball bearings are uncaged, it is likely that some will drop out of the races when the steering stem is lowered. Therefore, if the bearings are going to be reused, cover the ground beneath the assembly with a drop cloth.

7. With a hammer and punch, or the factory pin wrench, loosen the bearing adjuster nut until it can be turned by hand. Support the lower triple clamp with one hand while unscrewing the adjuster nut until it can be removed from the steering stem.

8. Remove the dust cover and the upper race of the top bearing set.

9. Carefully lower the steering stem out of the frame lug. The top bearing balls should remain in the frame lug race. The bottom bearing balls may fall out of the steering stem race as the stem is lowered.



INSPECTION AND INSTALLATION

1. Before removing them, note the number of balls fitted to each race. The number and size may be different for the top and bottom races.

2. Remove the balls and wash them in a suitable solvent. Clean off the bearing races as well.

3. Inspect the bearing balls for rust, pitting, indentations, flat spots, or cracks. Rather than replacing individual damaged balls, both ball sets should be replaced, and the races as well.

4. The bearing race surfaces should be

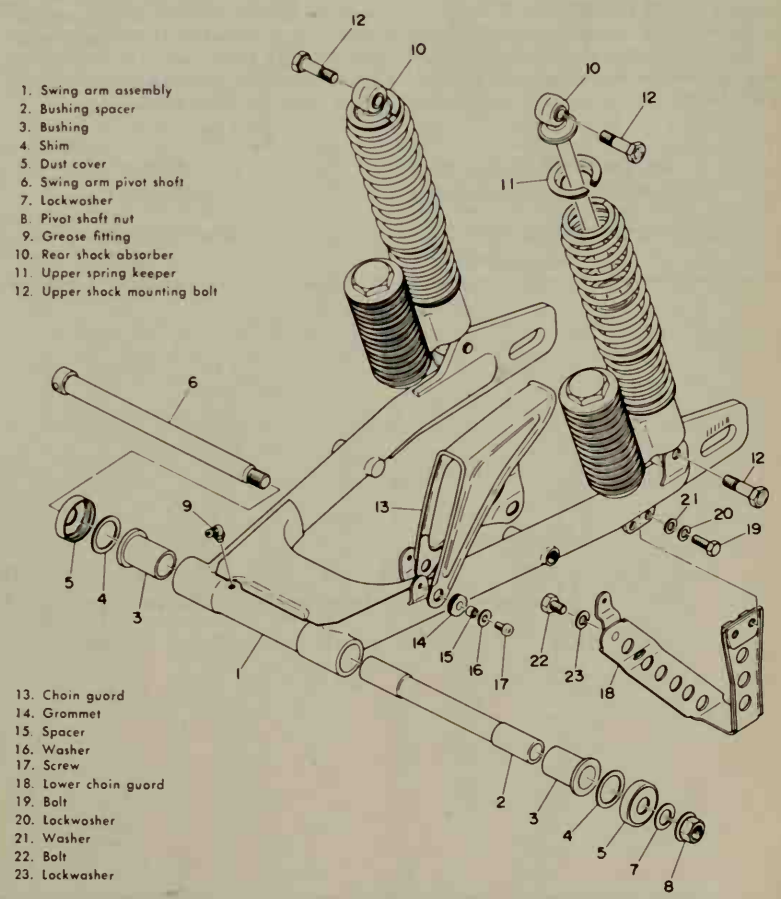
free of rust or corrosion, and smooth. Run your finger around the races. Any indented marks, ripples, or wear would indicate replacement of the races. If this is necessary, replace the balls as well.

5. The bearing races in the steering lug are removed with a hammer and punch. Installation should be made with a block of wood and a hammer to avoid damaging the races. The bearing race on the steering stem may have to be removed with a hammer and chisel.

6. To install, put a thick layer of bearing grease on the top frame lug race and on the steering stem race. Embed the bearings in the grease, ensuring that the correct number of balls are fitted. Install the steering stem replacing the top race, dust cover, and adjuster nut. Tighten the nut until slight resistance is felt, then adjust it so the steering stem will fall to either side of its own weight when released from a few degrees from the centered position.

7. Reassemble the rest of the front end in the reverse of the removal procedure. Check bearing adjustment as described above.



Swing Arm

The swing arm is mounted by means of bushings which tend to wear after many miles. The rate of wear will increase if the machine is used over rough terrain.

INSPECTION

1. To check the condition of the swing arm bushings, remove the rear wheel and sprocket and unbolt the lower shock absorber mounts.

2. Check for play by grasping the end of the swing arm firmly and attempting to move it from side-to-side. Play should be

Swing arm assembly (Courtesy Yamaha Int. Corp.)

nil. If there is more than 0.3–0.4 mm (0.012–0.016 in.) measured at the end of the swing arm, the swing arm should be removed and the bushings replaced.

3. Measure the distance between the top and bottom shock absorber mounts on both sides. The two measurements must be identical, or the swing arm will have to be replaced or fixed.

4. Check that the rear wheel mounting plates are parallel.

The swing arm is most likely to be damaged if the machine is operated for any length of time with a broken or otherwise defective shock absorber.

REMOVAL AND INSTALLATION

1. Remove the rear wheel, sprocket hub, and chain guard. Unbolt the shock absorbers from the swing arm.

2. Remove the swing arm pivot shaft nut. Push or tap out the shaft; turn the swing arm sideways, and remove it from the machine.

3. Remove the dust covers from the ends of the swing arm tube if fitted. Note the location and number of any shims beneath the dust covers.

4. Drive out the long bushing spacer (if fitted); tap out the bushings with a punch and hammer. Once the bushings are removed, they should be replaced. Check the spacer for wear and replace it if there is any evident.

5. Lubricate new bushings with a good chassis grease. Drift in bushings with a block of wood and a hammer.

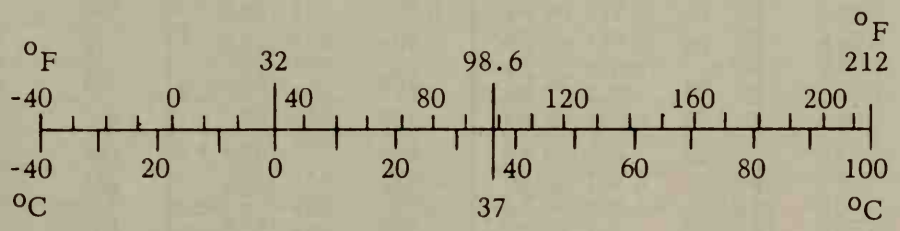
6. Install the swing arm on the machine. After tightening the swing arm pivot shaft nut, move the swing arm up and down to ensure that movement is smooth and effortless.

Rear Shock Absorbers

1. Shock absorbers are sealed units which cannot be disassembled. If defective, they must be replaced.

2. If a shock leaks oil from the shaft seal or is damaged in an accident (such as bent shaft, dented body, etc.), replace it.

3. To check a shock which is removed from the machine, place the bottom end on the ground and use the weight of your body to compress it as much as possible. Release the shock and note the rebound behavior. If the shock returns quickly at first, then slowly returns to the normal length, it is serviceable. If it returns to its normal length all at once, it should be replaced. Note that shock absorbers should always be replaced in pairs.



4. For "Thermal Flow" shock absorber service, refer to the "Maintenance" section.

Torque is expressed as either foot-pounds (ft./lbs.) or inch-pounds (in./lbs.). The metric measurement unit for torque is the Newton-meter (Nm). This unit—the Nm—will be used for all SI metric torque references, both the present ft./lbs. and in./lbs.

To convert foot-pounds (ft./lbs.) to Newton-meters: multiply ft./lbs. by 1.3

To convert inch-pounds (in./lbs.) to Newton-meters: multiply in./lbs. by .11

ENGLISH TO METRIC CONVERSION: FORCE

Force is presently measured in pounds (lbs). This type of measurement is used to measure spring pressure, specifically how many pounds it takes to compress a spring. Our present force unit (the pound) will be replaced in SI metric measurements by the Newton (N). This term will eventually see use in specifications for electric motor brush spring pressures, valve spring pressures, etc.

To convert pounds (lbs.) to Newton (N): multiply the number of lbs. by 4.45

ENGLISH TO METRIC CONVERSION: LIQUID CAPACITY

Liquid or fluid capacity is presently expressed as pints, quarts or gallons, or a combination of all of these. In the metric system the liter (l) will become the basic unit. Fractions of a liter would be expressed as deciliters, centiliters, or most frequently (and commonly) as milliliters.

To convert pints (pts.) to liters (l): multiply the number of pints by .47
To convert liters (l) to pints (pts.): multiply the number of liters by 2.1
To convert quarts (qts.) to liters (l): multiply the number of quarts by .95
To convert liters (l) to quarts (qts.): multiply the number of liters by 1.06
To convert gallons (gals). to liters (l): multiply the number of gallons by 3.8
To convert liters (l) to gallons (gals.): multiply the number of liters by .26

ENGLISH TO METRIC CONVERSION: PRESSURE

The basic unit of pressure measurement used today is expressed as pounds per square inch (psi). The metric unit for psi will be the kilopascal (kPa). This will apply to either fluid pressure or air pressure, and will be frequently seen in tire pressure readings, oil pressure specifications, fuel pump pressure, etc.

To convert pounds per square inch (psi) to kilopascals (kPa): multiply the number of psi by 6.89
